syllable-coding HVC units were alternately turned on and off at the syllable onset and offset times of the original song motif (upper middle panel). RA units in the model were driven by the HVC output through the synaptic connection strengths w_{ji} . For each of the four motor command variables (A , F , P , S), there were five units with different time constants (middle panel). The sum of the different temporal response profiles determines the time course of the motor command output (lower middle panel), which was sent to the syrinx model. The waveform of the synthesized song was then converted into a spectrogram (bottom panel). The spectrographic patterns of syllables (marked by boxes) were sampled and compared to the templates, yielding an evaluation r for each syllable that was then used for changing the weights w_{ji} .

Initially, the connection weights w_{ji} were set to small random values, so the syllables did not resemble the original song. After about 500 trials, the average correlation

HVC units. (middle panel) Responses of the units in RA. (lower middle panel) Four motor command variables. (bottom panel) Spectrogram of the synthesized song produced by the network.

FIGURE 33.9 Sonograms. (A) The original zebra finch song motif. (B) A song produced by the model after 500 trials using

the zebra finch song A as the template. (C) A song produced after 500 trials using the model song B as the template.

between the original and synthesized syllables reached about 0.8 (figure 33.10). The final synthesized song motif sounded more similar to the tutor song than the random initial song. As shown in the spectrograms (figure 33.9), the overall frequency profiles of the syllables were similar, although the detailed features in the spectrogram, such as harmonic structures and frequency modulation patterns, were not accurately reproduced.

LEARNING A SYNTHESIZED SONG There are two possible reasons for the imperfect replication of the zebra finch song syllables. One is that our model of the syrinx and the motor control network were much more primitive than those of a real zebra finch, and therefore precise mimicry was impossible. Another is that the reinforcement learning procedure converged to a suboptimal solution. In order to differentiate these possibilities,

FIGURE 33.10 Learning curves for the song learning model. Two different learning curves are shown, one using a zebra finch song as the tutor (dashed line) and the second using a synthesized song generated by another model as the tutor (dotted line). On each trial, a new set of weight perturbations was chosen, a song produced, and an evaluation carried out as described in the text. The evaluation shown here is the correlation between the syllable and its corresponding template. The curves represent the average evaluation of 50 syllables (10 syllables per song; 5 simulation runs).

we tested the performance of the model when the target song could be exactly reproduced by taking a set of syllable templates from a synthesized song motif and training another model from a random start. The correlation after 500 trials was 0.94 (dotted line in figure 33.10) and the song sounded quite similar to the tutor model as judged by human ears (see figure 33.9B,C). This result implies that the relatively low performance using a real zebra finch song as a template was mainly due to the differences between the vocal system of the real bird and that of the model. However, even with the synthesized song, the reinforcement learning algorithm did not converge to the optimal solution with a correlation of 1.0. Note that imperfect replication of syllables and the resulting individual variability of songs are also seen in real birds.

Discussion

The primary question addressed by our model of song learning is whether a relatively simple reinforcement learning system could converge to a tutor song within the number of trials that are available to a real zebra finch. The model is based on specific hypotheses for how the computational problems could be solved in a way that is consistent with the neural responses that have been observed in song control nuclei. The simulations demonstrate that the proposed learning system can satisfy these constraints and imitate birdsong.

Many simplifying assumptions were made in the present network model: Syllables were unary coded in HVC; the sound synthesizer was much simpler than a real syrinx; simple spectrographic template matching was used for syllable evaluation. However, it is possible to replace these simplified modules with more biologically accurate ones as warranted by further experimental data. Since the number of learning trials needed to reach convergence in the present model was many fewer than the number of vocalizations that occur during real birdsong learning, which have not been counted in the zebra finch but number many thousand, there is adequate margin for elaboration.

Additional experiments are needed to test and improve the model, as outlined in the following subsections.

BLOCKING DA INPUT FROM AVT We have suggested that dopaminergic input from AVT to area X could be used for selection of a particular auditory input as a song template. Lesion or reversible block of the dopaminergic system in AVT should disrupt memory of tutor syllables if this hypothesis is true. Injection of dopaminergic agonist or antagonist into area X during tutor song presentation should affect selection of songs to be learned. If confirmed, this method would provide strong evidence that the song templates are stored in the anterior forebrain pathway.

TEST OF MODULATION AND PLASTICITY INDUCED BY LMAN We assumed that NMDA-type synaptic input from LMAN to RA modulated the non-NMDA-type synaptic input from HVC to RA. There has been no direct experimental evidence for plastic changes in RA synapses induced by input from LMAN. Further experiments in slice preparations could reveal when and how such plasticity is induced, or could indicate that such plasticity is not plausible. Another approach is electric stimulation of LMAN in young, singing birds. If altered activity in LMAN results in perturbation of ongoing song or plastic change in the song after perturbation, that would suggest the existence of modulatory or plastic mechanisms *in vivo*.

SUPPRESSION OF AUDITORY RESPONSE IN HVC DURING SINGING In HVC neurons that have both auditory and motor responses, the auditory responses are suppressed during and soon after the bird is singing (McCasland and Konishi, 1981; McCasland, 1987). If the suppression is complete and occurs in young birds, we would have to reconsider the use of auditory feedback in the model. One possibility is that the suppression is due to the same mechanisms that induce hyperpolarization in

HVc neurons with the auditory stimulus of the bird's own song (Lewicki, 1996). This may help in narrowing the auditory selectivity of the HVc neurons.

DELAY IN AUDITORY FEEDBACK We assumed that each vocalized syllable was evaluated separately, but this approach may not be possible if there is significant overlap in the motor and auditory responses to adjacent syllables. The auditory response latency is about 30 ms in HVc and 50 ms in LMAN in anesthetized birds (Williams, 1989). If the latency is similar in awake birds, by the time the anterior forebrain pathway processes the auditory feedback, the motor units in HVc and RA should be generating the next syllable. In order to utilize the delayed evaluation signal, the synapses from HVc to RA have to use an "eligibility trace" for plasticity (Barto, Sutton, and Anderson, 1983). Examples of possible biological implementation of eligibility traces can be seen in Houk, Adams, and Barto, (1994), and Schweighofer, Arbib, and Dominey (1996).

Recently, a new hypothesis was proposed for a "forward model" within HVc that predicts the auditory outcome from the HVc motor output. The predicted auditory outcome is then used for immediate reinforcement of ongoing motor activity instead of the actual auditory feedback (Troyer, Doupe, and Miller, 1996). However, it may be difficult for such prediction of auditory outcome to be reliably performed within HVc while the connection from HVc to RA is changed by learning.

FEEDBACK CONNECTION IN THE ANTERIOR FOREBRAIN PATHWAY Recently, novel axonal connections were found from RA to DLM (Wild, 1993) and from LMAN to area X (Vates and Nottebohm, 1995; Nixdorf-Bergweiler, Lips, and Heinemann, 1995). Although we did not take into account these possible feedback connections within the AFP, they are still consistent with our basic assumption that there is no feedback connection back to HVc in the AFP.

The finding of the novel connection from LMAN to area X raises a possibility that correlation between perturbation and evaluation, which is the main factor of stochastic learning, is taken at the level of area X instead of in LMAN as we assumed. It has been shown that the connections from LMAN through area X to DLM (Vates and Nottebohm, 1995) and from DLM through LMAN to RA (Johnson, Sablan, and Bottjer, 1995) are topographically organized. This organization would enable the activity pattern in LMAN to be correlated with the syllable evaluation in area X and then sent back to LMAN through DLM to alter the next activity pattern in LMAN. Together with the finding that the ventral and

middle parts of RA differentially control the dorsal and ventral syringeal muscles and that these muscles control the air flow and the fundamental frequency, respectively (Goller and Suthers, 1995), it is possible that there are distinct channels within the AFP that are involved in evaluation and modulation of different aspects of vocalization. However, data on the activity of AFP neurons during singing would be necessary to test these possibilities.

Conclusions

In this chapter, we have identified computational mechanisms that could account for birdsong learning and shown how these mechanisms could be supported by the known anatomy of the avian brain. We then focused on the issue of sensorimotor learning and tested our specific hypothesis that the anterior forebrain pathway works as a reinforcement learning system. The current theory and simulation results given here could be regarded as an "existence proof" for one solution to the song-learning problem, but it does not exclude other possible solutions. Nevertheless, this is the first computational model of the entire song-learning system that is able to replicate realistic birdsongs. Because the model was based on the recent experimental findings, especially those from the anterior forebrain pathway, experimental tests of the proposed model should provide a better understanding of the mechanisms of song learning and, more generally, the neural principles underlying the acquisition of novel motor patterns based on sensory experience.

ACKNOWLEDGMENTS We thank M. Lewicki for the zebra finch song data and M. Konishi, D. Margoliash, A. Doupe, M. Lewicki, E. Vu, D. Perkel, G. Striedter and S. Volman for their helpful discussions.

Introduction

EMILIO BIZZI

This section addresses a series of central issues in motor control, ranging from motor planning and execution to motor learning.

Planning and execution of limb movements

A number of studies in humans and monkeys have demonstrated that the posterior parietal cortex has a role in programming actions and in transforming sensory signals into plans for motor behaviors (Mountcastle et al., 1975; Andersen, Brotchie, and Mazzoni, 1992; Mazzoni et al., 1996; Snyder, Baptista, and Andersen, 1997). Functionally different subdivisions of the posterior parietal cortex have been identified. Among these subdivisions, there is an area specialized for saccades, the lateral intraparietal area (LIP), and a posterior parietal region (PRR) specialized for planning reaching movements. A third area is the anterior intraparietal area (AIP), which is specialized for grasping (Sakata et al., 1997).

Andersen and colleagues (see chapter 36) have shown how the different sensory modalities that originally are represented in different coordinate frames are brought together in the areas of the posterior parietal cortex. LIP and PRR areas encode the spacial location of visual and auditory signals using a common reference frame, that of the eye. The neurons of these areas code a goal for movement in multiple coordinate frames (eye, head, body, and the world). Depending on how these cells are read by other brain areas, different coordinate transformations can be accomplished by the same population of neurons.

Among the brain areas, those of the frontal lobe, especially the premotor cortex, receive signals from the posterior parietal cortex. Metelli and associates (1994)

showed that the parietal area AIP and the premotor areas anatomically are connected reciprocally. Sakata and coworkers (1997), who have studied the properties of the AIP neurons, showed that many AIP neurons are selective for object shape and size. In addition, Sakata and associates described neurons that are active during object fixation and grasping movements executed under visual guidance. These neurons do not discharge when the same movement is performed in darkness.

Given the connectivity between the parietal cortex (AIP) and the premotor areas of the frontal lobe, it is not surprising that the neurons of the premotor areas discharge actively during grasping. However, as shown by Rizzolatti, Fogassi, and Gallese in chapter 38, the prefrontal neurons are profoundly different from those in the parietal cortex. The prefrontal neurons are active when grasping is performed, but, remarkably, they also are active when the movement is performed with different effectors, such as the right and the left hand, or the mouth. Other neurons are selective for grasping with a specific grip type.

According to these authors, these neurons store specific knowledge about an action and indicate how to implement it. They represent a “vocabulary” of actions. The existence of anatomic connectivity between the premotor area and the classical motor area 4 facilitates the selection of the most appropriate combination of movements. In addition, the presence of these neurons simplifies the association between a given sensory stimulus, such as a visually presented object, and the appropriate motor response toward it.

In addition to the various types of grasping neurons, there is another class of neurons that becomes active both when the monkey performs an action and when it observes a similar action made by another monkey or by the experimenter. These neurons have been named “mirror neurons.” Rizzolatti, Fogassi, and Gallese have related this important and novel observation to a basic system of recognition of actions and the creation of an internal copy of actions.

In chapter 37, Georgopoulos deals with planning and emphasizes that to study the neural mechanisms of cognitive motor processing, a multiplicity of approaches is needed. Behavioral, neurophysiologic, and imaging methods all provide the crucial insights into the neural processes subserving the production of movement. Examples illustrating that each of these methods affords only a partial view of the whole are described.

In chapters 36, 37, and 38, Andersen and associates, Georgopoulos, and Rizzolatti, Fogassi, and Gallese describe the activities of parietal and frontal neurons that clearly are related with some aspect of motor planning. Bizzi and Mussa-Ivaldi (chapter 34) and Jordan and

Wolpert (chapter 42) also address the question of planning but focus mainly on the processes that transform a motor plan into the signals that activate the muscles.

To execute movements, the central nervous system must transform information about a small number of variables (direction, amplitude, and velocity) into a large number of signals to many muscles. Any transformation of this type is “ill-posed” in the sense that an exact solution either is not available or is not unique. For instance, if the goal is to move the hand from an initial position (A) to a point (B) in space, then there are a number of possible hand trajectories that could achieve this goal; the solution of this elementary motor problem is not unique. Even after the central nervous system has chosen a particular path for the hand, its implementation can be achieved with multiple combinations of joint motions at the shoulder, elbow, and wrist. Again, the solution is not unique. Finally, because there are many muscles around each joint, the net force generated by their activation can be achieved by a variety of combinations of muscles.

How the central nervous system of vertebrates handles the staggering number of mechanical variables involved even in the simplest movement is one of the central problems in motor control. In their chapter, Jordan and Wolpert describe the computational models that have been proposed by a number of investigators in the last few years.

The complexity inherent in controlling so many degrees of freedom has led researchers to propose that the nervous system must have developed ways to simplify this problem. In their chapter, Bizzi and Mussa-Ivaldi present evidence supporting the idea that the transformations leading to the execution of a motor plan are implemented by a small number of control modules. Recent experiments in the spinalized frog have suggested that these control modules may be organized in the spinal cord as simple synergies of spring-like muscles. Subsequent work has revealed that an extensive variety of movements can be obtained from a simple linear summation of these control modules.

Planning and execution of eye movements

Many regions in the primate brain have been identified where neuronal activity correlates with the generation of saccades. These regions include the frontal and parietal cortices, the basal ganglia, the cerebellum, and the brain stem. A key structure of the saccadic system is the superior colliculus. Areas in the cerebral cortex and basal ganglia project directly to the superior colliculus, which can be seen as a location for the coordination of the varied inputs from the forebrain and as the location for the

transformation of these inputs into outputs for the control of eye movements. In chapter 40, Wurtz and associates describe the different types of neurons found within the superior colliculus, the importance of the map of saccadic vectors on the colliculus, and the significance of the change in the population activity within the map for the generation of eye movements. A key point of this chapter is the discussion of the significance of the delay activity in the buildup and fixation neurons. Wurtz and colleagues regard the delay activity observed in collicular neurons as part of the preparation to move.

Another important point is the comparison of the activity of neurons in the superior colliculus with those in the cortex that project to the superior colliculus. One of the most striking observations is that the same type of activity can be identified in both cortex and superior colliculus. This result supports the idea of a distributed processing in which a given transformation does not occur in a particular area but rather progresses across a series of regions.

Motor learning

The chapters by Ghez and associates (chapter 35), Hikosaka and colleagues (chapter 39), and Wilson (chapter 41) deal with the cellular substrates of motor learning. Hikosaka and colleagues describe the brain areas that become active during the acquisition of a visuomotor sequence. He shows that in the early stages of learning of a sequence, there is activation of the supplementary motor area (SMA) and the dorsolateral prefrontal cortex. These areas act together with the anterior part of the basal ganglia. Subsequently, the posterior part of the basal ganglia and the dentate nucleus of the cerebellum become active. Hikosaka also demonstrates that the learning of the sequence was disrupted only partially by the inactivation of one of these areas, suggesting that multiple regions subserve learning concurrently.

Another form of learning is navigation, which involves establishing the initial position of the animal, updating this information by keeping track of self-movement, identifying landmarks, and establishing spacial orientation with respect to them. In 1978, O'Keefe and Nadel outlined several basic systems for rodent's navigation, with the hippocampus as the site of the cognitive map for navigation.

In his chapter, Wilson describes in detail the neural systems that are involved in the acquisition and maintenance of the sense of place and directions. He demonstrates that directional and place information is maintained by distinct hippocampal and thalamic subsystems that are capable of incorporating self-motion signals as well as extrinsic cue information. Interestingly, these sig-

nals are dependent on prior experience demonstrating their dependence from memory.

Ghez and collaborators in chapter 35 examine the neural patterns of activity that are established during different types of motor learning. They describe the internal representations and the learning that underlie the development of accuracy in point-to-point movements of the arm. The observation presented in this chapter demonstrates that reaching for visual targets quickly and accurately depends on three internal representations, each of which is adjusted through sensory feedback. Learning to produce accurate movements involves distinct processes based on visual feedback. In contrast, the transformation of a motor plan coded in extrinsic space coordinates into a system of intrinsic coordinates depends critically on proprioception.

Given that many motor control problems involve interacting with unexpected circumstances in the environment, successful performance is dependent on the motor system's ability to adapt. Through adaptation, the motor control system is able to maintain and update its internal knowledge of external dynamics. In their chapter, Jordan and Wolpert discuss different approaches to the problem of motor learning, such as direct inverse modeling, feedback error learning, distal supervised learning, reinforcement learning, and unsupervised bootstrap learning. All these approaches provide mechanisms for sensory motor transformations, but they differ in the kind of data that they require.

34 Toward a Neurobiology of Coordinate Transformations

EMILIO BIZZI AND FERDINANDO A. MUSSA-IVALDI

ABSTRACT The authors discuss a perspective in motor control that is based on the distinction between planning and execution of motor behaviors. This distinction has emerged from experimental observations that suggest that the central nervous system plans movements in terms of spatial or extrinsic coordinates rather than body-centered coordinates. What, then, are the processes that transform a motor plan into the signals that activate the muscles? The authors review a number of theoretical and experimental findings that suggest that the coordinate transformations leading to the execution of a motor plan are implemented by a small number of control modules. In particular, some recent experiments in the spinalized frog have suggested that these control modules may be organized by the spinal cord as simple synergies of spring-like muscles. Subsequent theoretical work has revealed that a wide variety of motor control policies can be obtained from a simple linear combination of these few control modules. The computational framework for representing the generation of movement by a combination of independent modules is presented in this chapter. Finally, the implications of this modular approach for our understanding of motor learning and adaptation are discussed.

In this chapter, we address a conundrum that has long faced investigators in motor control: If movements are specified by the central nervous system (CNS) in terms of goals, as psychophysical evidence seems to imply, what are the processes in the CNS that transform the neural representation of these goals into signals that activate the muscles? In the past few years, psychophysical and electrophysiologic observations made by a number of investigators have indicated that motor goals as simple as reaching and pointing are planned by the CNS in terms of extrinsic coordinates representing the motion of the hand in space. In the first part of this chapter, we review the evidence that motor behavior is represented in the higher centers of the brain in terms of extrinsic coordinates. In the second part, we propose a novel hypothesis describing one possible way in which motor plans could be transformed into motor commands.

Evidence for motor planning in spatial (extrinsic) coordinates

In which coordinate frames does the CNS represent movement? Morasso (1981) suggests that the planning of arm movements is carried out in extrinsic coordinates that represent the motion of the hand in space. Morasso instructed human subjects to point with one hand to different visual targets that were activated randomly. His analysis of the movements showed two kinematic invariances: (1) the hand trajectories were approximately straight segments, and (2) the tangential hand velocity for different movements always appeared to have a bell-shaped configuration—the time needed to accelerate the hand was approximately equal to the time needed to bring it back to rest. Because these simple and invariant features were detected in the coordinates of the hand only, these results suggest that CNS planning takes place in terms of hand motion in space. Morasso's observations were extended to more complex curved movements performed by human subjects in an obstacle avoidance task (Abend, Bizzi, and Morasso, 1982). Again, kinematic invariances were present in the hand and not in the joint motion. Later, Flash and Hogan (1985) showed that the kinematic behavior described by Morasso (1981) and Abend, Bizzi, and Morasso (1982) could be derived from a single organizing principle based on optimizing endpoint smoothness. Interestingly, their mathematical model is compatible with a hypothesis based on planning in space but not with that based on joint coordinates.

The idea that movements of the hand are planned by the CNS in terms of extrinsic coordinates is related to the hypothesis that the planning and execution of movements constitute two separate stages of information processing (Bernstein, 1967; Hogan et al., 1987; and Ghez et al., chapter 35, this volume). According to this view, during planning, the brain is concerned with establishing movement kinematics—that is, a sequence of positions that the hand is expected to occupy at different times within the extrapersonal space. During execution, the dynamics of the musculoskeletal system are controlled

to enforce the planning of movements within different environmental conditions.

This separation between planning and execution (or between kinematics and dynamics) has been challenged by Uno, Kawato, and Suzuki (1989), who have suggested that the kinematic features observed by Morasso may be accounted for by a model in which the rate of change of joint torque, rather than endpoint smoothness, is minimized. In essence, these authors proposed that the observed kinematics might be a “side effect” of the computational processes underlying the control of dynamics.

In contrast with this view, recent experimental findings by Flash and Gurevich (1992) and by Shadmehr and Mussa-Ivaldi (1994) have demonstrated that the kinematics of movement indeed are planned independently of the dynamic conditions in which movement occurs. Shadmehr and Mussa-Ivaldi (1994) asked human subjects to execute movements of the hand in different directions while holding the handle of a two-joint planar robot. At the beginning of the experiment, the robot acted as a passive device, and the subject produced straight-line hand movements (as described in Morasso’s experiment). In a subsequent stage of the experiment, the robot was programmed to generate a field of forces that depended linearly on the measured velocity of the hand.

The effect of the field was rather complex, consisting of a combination of destabilizing forces and a viscous drag in two orthogonal directions. At first, subjects reacted to the unexpected field with a visibly perturbed trajectory of the hand. Subjects then were asked to perform several target acquisition movements within the field of forces, and they were not given any instructions regarding hand trajectory.

Gradually, the kinematics of the hand movements returned to the original straight line with a bell-shaped tangential velocity profile, as observed before the onset of the perturbing field. Flash and Gurevich (1992), who used a spring-like load instead of a velocity-dependent field as a perturbation, observed a similar adaptive behavior.

Thus, in the experiments by Shadmehr and Mussa-Ivaldi and Flash and Gurevich, the basic kinematics—that is, the straight line trajectories and bell-shaped velocity profiles—were restored at the end of the adaptation period despite a totally changed dynamic environment.

Clearly, these findings are not compatible with the idea that the movement kinematics are derived from a single optimization principle applied to the dynamics of the motor system. On the contrary, the results on the adaptation to external force fields strongly suggest that

movement kinematics are programmed as a desired trajectory to be enforced in different dynamic conditions.

In addition to the psychophysical evidence, recordings from cells in cortical and subcortical areas of monkeys have shown a correlation between the cells’ firing pattern and direction of the hand’s motion (Georgopoulos, Kettner, and Schwartz, 1988a,b; Kalaska et al., 1989; Caminiti, Johnson, and Urbano, 1990; Georgopoulos, see chapter 37, this volume). It appears that the activity of certain classes of cortical cells in the motor cortex is represented in spatial coordinates without any specification about how muscles are to be engaged to produce the forces necessary for the movement.

Taken together, the psychophysical and electrophysical evidence points toward a hierarchical organization of the motor system, with the higher centers of the CNS representing motor goals in spatial coordinates. The next step, of course, is the transformation of the motor goals into impulses for the large number of muscles that are activated simultaneously during the execution of even the simplest kind of limb movement.

Execution of planned actions: The production of muscle’s forces

To execute movements, the CNS must transform information about a small number of variables (direction, amplitude, and velocity) into a large number of signals to many muscles.

Any transformation of this type is “ill-posed” because an exact solution might not be available or unique. For instance, if the goal is to move the hand from an initial position [A] to a point [B] in space, then clearly there are a number of possible hand trajectories that could achieve this goal: the solution of this elementary motor problem is not unique. Even after the CNS has chosen a particular path for the hand, its implementation can be achieved with multiple combinations of joint motions at the shoulder, elbow and wrist—again, the solution is not unique. Finally, because there are many muscles around each joint, the net force generated by their activation can be achieved by a variety of combinations of muscles.

How the CNS of vertebrates handles the staggering number of mechanical variables involved in even the simplest movement is one of the central problems in motor control. Even a simple task, such as a reaching movement of the arm toward an object, involves the simultaneous activation of many thousands of motor units belonging to a number of muscles. The complexity inherent in controlling so many degrees of freedom has led us and a number of other researchers to propose that

the nervous system must have developed ways to simplify this problem.

A variety of proposals have been made to explain these complexities. For instance, Hollerbach and Atkeson (1987), inspired by work in robotics, have suggested that the CNS first derives the motion of the joints from the planned path of the limb's endpoint (inverse kinematics). Next, the CNS computes the necessary joint torques (inverse dynamics) and then distributes the torques to a number of muscles. This hypothesis rests on the assumption that the CNS can estimate accurately limb inertia, center of mass, and the moment arm of muscles about the joints. This line of thinking seems to us improbable because the implied feedforward computations would lead to large motor instabilities every time the small errors in evaluating the various parameters occur. Alternative proposals have been made that do not depend on the solution of the complicated inverse dynamics problem. Specifically, it has been proposed that the CNS may transform the desired hand motion into a series of equilibrium positions (Bizzi et al., 1984). The forces needed to track the equilibrium trajectory result from the intrinsic elastic properties of muscles and from local feedback loops (Feldman, 1974; Bizzi, Polit, and Morasso, 1976, 1992; Hogan, 1984, 1985).

In the past few years, Bizzi, Mussa-Ivaldi, and Giszter (1991), Giszter, Mussa-Ivaldi, and Bizzi (1993), Mussa-Ivaldi, Giszter, and Bizzi (1994), and Saltiel, Tresh, and Bizzi (1998) have asked a specific question. Is the motor behavior of vertebrates based on simple units (motor primitives) that can be combined flexibly to accomplish a variety of motor tasks? This fundamental and long-standing question was addressed by investigating the spinal cord of frogs and rats with an array of approaches, such as microstimulation, *N*-methyl-D-aspartate (NMDA) iontophoresis, cutaneous stimulation of the hindlimb, and supraspinal stimulation. With these techniques, evidence for a modular organization of the frog and rat's spinal cord has been provided.

Evidence for spinal cord modules

A module is a functional unit in the spinal cord that generates a specific motor output by imposing a specific pattern of muscle activation. One way to elicit a spinal module is through microstimulation of the spinal cord in spinalized frogs. Bizzi, Mussa-Ivaldi, and Giszter (1991) and Giszter, Mussa-Ivaldi, and Bizzi (1993) elicited the activation of the leg's muscles by microstimulating the lateral and intermediate neuropil zone of the lumbar spinal cord.

To measure the mechanical responses of the activated muscles, Bizzi, Mussa-Ivaldi, and Giszter (1991) attached the right ankle of the frog to a six-axis force transducer, as shown in figure 34.1. The transducer held the ankle approximately level with the acetabulum. The transducer was mounted on a two-axis Cartesian manipulator, and the Cartesian location of the frog's ankle was set using this manipulator. The *xy*-plane corresponded approximately to the horizontal plane. In the experiments described, only the *x* and *y* components were considered.

Following the microstimulation of the spinal cord, Bizzi and associates observed a change in the forces at the ankle after a latency of between 30 and 150 msec. (Most response latencies were at approximately 100 msec.) The forces rose to a plateau level and then declined to the baseline level after a variable period (300 msec to 2 sec) after the termination of stimulation. At each ankle location, the net force vector, \mathbf{F} , obtained in response to stimulation, was expressed as the sum of two components—the “resting” force vector, \mathbf{F}_r , and the “active” force vector, \mathbf{F}_a :

$$\mathbf{F} = \mathbf{F}_r + \mathbf{F}_a \quad (1)$$

The resting force vector corresponded to the force measured before the onset of the stimulus. The active force vector, $\mathbf{F}_a = \mathbf{F} - \mathbf{F}_r$, represented the additional force induced by our stimulus. The active field was generated only by those muscles directly or indirectly activated in response to stimulation.

As the electrode penetrated deeper into the cord, the orientation of the “active,” above-baseline force vector recorded at a given leg position generally remained constant. Its magnitude usually varied, reaching a peak at the site of lowest threshold.

To record the spatial variations of forces generated by the leg muscles, Bizzi and colleagues followed a three-part procedure. First, they placed the frog's leg at a location within the leg's workspace. Second, they stimulated a site in the spinal cord and recorded the direction and amplitude of the elicited isometric force at the ankle. Third, they repeated the stimulation procedure with the ankle placed at each of 9 to 16 locations. These locations sampled a large portion of the region of the horizontal plane that could be reached by the frog's ankle (i.e., the leg's workspace). At each location, they stimulated the same site in the spinal cord and recorded the force vector, $\mathbf{F} = (\mathbf{F}_x, \mathbf{F}_y)$, at the ankle. Although the site of spinal cord stimulation was constant throughout, they found that the elicited force vector varied as they placed the leg at different locations. These changes in force throughout the workspace resulted from a variety of mechanical factors, such as the

FIGURE 34.1 The apparatus and method of construction of a force field. (A) A collection of forces are recorded at several different spatial locations (black dots). (B) A minimum perimeter (Delaunay) tessellation of the nine points is constructed. Within each triangle, vectors are estimated using an exact linear interpolation based on the three corner vectors. Thus, vector *v* is calculated using vectors at vertices *a*, *b*, and *c*. (C) The interpolated field is used to find any equilibrium point (EP). (D) On the left, the interpolated force field is shown in relation to the frog in the apparatus. On the right, this representation is

reduced to a stylized construction that is used to express the relation of frog axis and leg to the interpolated force field in the remaining figures. (E) The apparatus. The spine is clamped and the pelvis is held clamped by restraints (not shown). With an electrode in the spinal gray matter, the mechanical response to stimulation is recorded at the force sensor, which is attached to the limb at the ankle. The limb configuration is constrained fully by the pelvic restraint and the force sensor. (From Giszter, Mussa-Ivaldi, and Bizzi, 1993.)

length, moment arms, and viscoelastic properties of the muscles. In addition, reflex modulation of the muscles' activations played a role in the development of the forces at the ankle.

The collection of the measured forces corresponded to a force field (figure 34.1). Remarkably, in most instances (80%), the spatial variation of the measured force vectors resulted in a field that was at all times both convergent and characterized by a single equilibrium point (i.e., a point at which the amplitude of the F_x and F_y force components was zero). This equilibrium point represented the locus at which the leg would have been at steady state if it were free to move. The temporal evolu-

tion of the total force field caused a smooth movement of the equilibrium point from its position at rest to a new position at peak force magnitude and then back to the resting position. This motion of the equilibrium point constitutes what has been called the "virtual trajectory." The virtual trajectory is defined as the trajectory of positions at which the leg would experience no net force (figure 34.2).

Bizzi and coworkers and Giszter and associates found that the active-field data fell into a few classes or force field types (figure 34.3). After mapping most of the premotor area of the lumbar cord, they reached the conclusion that there are at least four areas from which four

FIGURE 34.2 Comparison of actual and virtual trajectory. (A) Force field measurements. Shown is the virtual trajectory of equilibrium points (upper left), which derives from the time course of the total convergent force field shown at peak amplitude. The active field (lower left) had a pattern of forces that would specify a flow moving caudally and medially. The relation of the trajectory to the frog's body is shown schematically at lower right. (B) Trajectory measurements. Three sample limb trajectories from the suspended limb are shown. These were recorded at 30 Hz using a video system. We related the

kinematic data to the grid of points used to collect the forces sampled for the field. The three trajectories begin at different locations in the grid because of different initial resting fields as a result of the leg's suspension (see text). The actual pattern of movement is predicted well by the total field. This was especially evident in the first trajectory, where resting equilibria almost coincide. The direction of the movement was predicted well by the active pattern in those trajectories where initial resting postures differed. (From Giszter, Mussa-Ivaldi, and Bizzi, 1993.)

distinct types of convergence force fields (CFFs) are elicited. Within each region, a qualitatively similar set of x and y forces were produced. This map of postures is shown in figure 34.3.

Force fields elicited by chemical stimulation

With electrical stimulation, it is not clear at which level the cells of the spinal cord are stimulated; somas, dendrites, axons, and nerve terminals all can be depolarized by current. For this reason, Saltiel, Tresh, and Bizzi (1998) induced force output from the spinal cord of the frog by using a compound that is known to activate only somas and dendrites. NMDA microiontophoresis was used with current and duration parameters expected to produce a spread estimated at a 150- to 270-mm radius.

This study confirmed that the spinal cord produces a limited number of discrete motor outputs. NMDA iontophoresis was applied to the lumbar spinal cord gray

while monitoring the isometric force output of the ipsilateral hindlimb at the ankle. Tonic and rhythmic forces were generated. The distribution of force orientations was quite comparable to that obtained with electrical stimulation at the same sites. The map of tonic responses revealed a topographic organization; each type of force orientation was elicited from sites that grouped together in zones at distinct rostrocaudal and depth locations. Taken together, these results support the concept of a modular organization of the motor system in the frog's spinal cord and delineate the topography of these modules.

Mapping rhythmic forces showed that each was elicited from two or three regions of the cord. These results suggest that the different types of responses organized within the spinal cord might be combined together to create complex behaviors, such as those produced during rhythmic pattern generation. One mechanism by which these responses might be combined flexibly to create more complex behaviors is described in the next section.

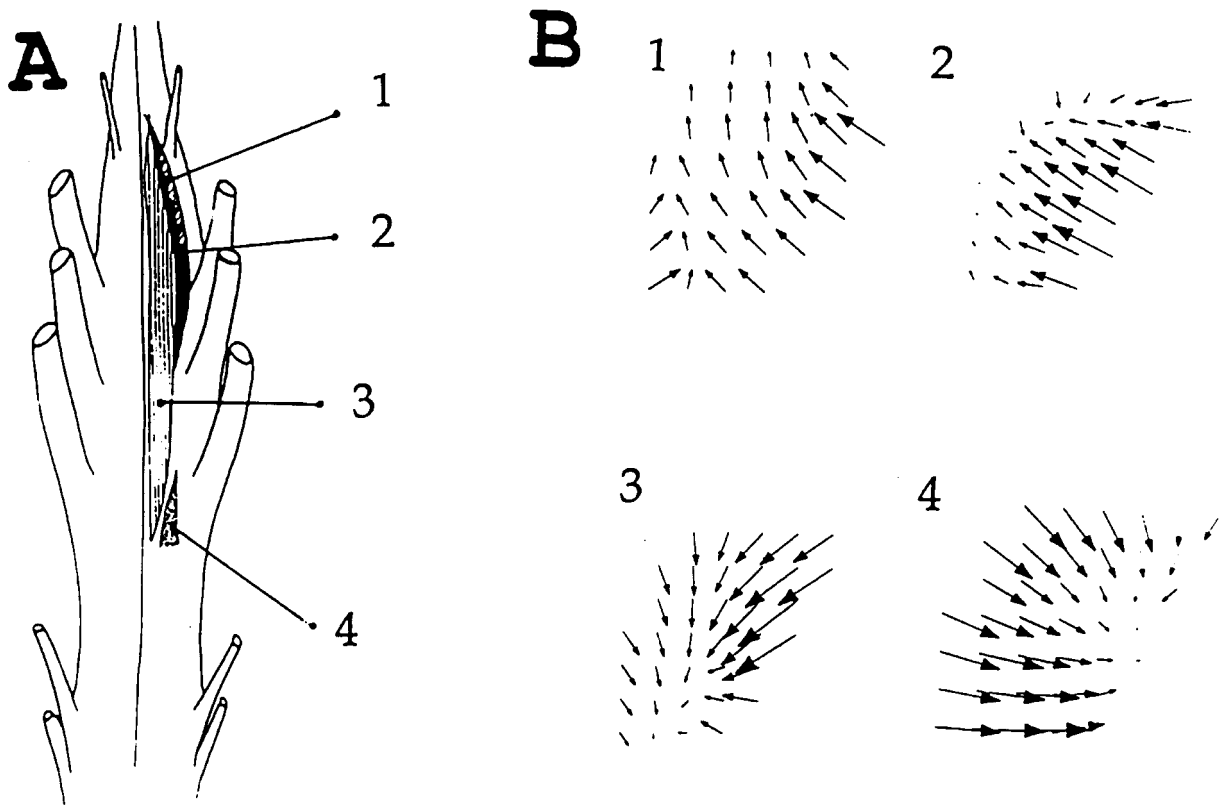

FIGURE 34.3 (A) Regions of the lumbar spinal cord containing the neural circuitries that specify the force fields (1–4). Within each region, similar sets of convergence force fields (CFFs) are produced. The diagram is based on 40 CFFs elicited by microstimulation of premotor regions in three spinalized frogs. (B) Four types of CFFs. To facilitate comparison among CFFs recorded in different animals, we subtracted the

passive force field from the force field obtained at steady state. Passive field represents the mechanical behavior generated by the frog's leg (recorded at the ankle) in the absence of any stimulation. The force field is at steady state when the forces induced by the stimulation of the spinal cord have reached their maximal amplitude. (From Bizzi, Mussa-Ivaldi, and Giszter, 1991.)

Vector summation of force fields

One of the most remarkable observations derived from the microstimulation of the frog spinal cord has been that the fields induced by the focal activation of the spinal cord follow a principle of vectorial summation. Specifically, Mussa-Ivaldi, Giszter, and Bizzi (1994) investigated vectorial summation with the following experimental paradigm. First, a focal electrical stimulation was delivered to a site, A , of the spinal cord and the subsequent active field $F_A(x)$ was determined by measuring a set of force vectors at distinct ankle locations. Following the measurement of $F_A(x)$, a second electrical stimulation was applied to a different site, B , and a field $F_B(x)$ was derived. From these two fields, their sum, $F_S(x) = F_A(x) + F_B(x)$, was computed at all the sample points. Finally, another active field, $F_{\&}(x)$, was measured by stimulating the sites A and B simultaneously. When Mussa-Ivaldi, Giszter, and Bizzi compared the “costimulation fields,” $F_{\&}(x)$, with the corresponding “summation

fields,” $F_S(x)$, they found that in 80% of cases, the two fields were equivalent (figure 34.4).

The observation that force fields sum vectorially suggests a way to relate natural movements to spinal cord microstimulation. Diverse neural signals conveyed by afferent inputs or descending tracts may gain access to the premotor areas described by Bizzi, Mussa-Ivaldi, and Giszter (1991), Giszter, Mussa-Ivaldi, and Bizzi (1993), and Saltiel, Tresh, and Bizzi (1998) and in this way specify the activation of a set of muscles. Physiologic movements result from patterns of neural activity distributed by afferent fibers or by descending branching fibers throughout fairly wide regions of the spinal cord. The activity conveyed by these branches may stimulate local clusters of cells that in turn generate force fields. Our assumption is that these fields sum like the convergent force fields generated by our electrical or chemical stimulation, leading to the possibility that a wide range of behaviors can be created by the summation of these different force fields.

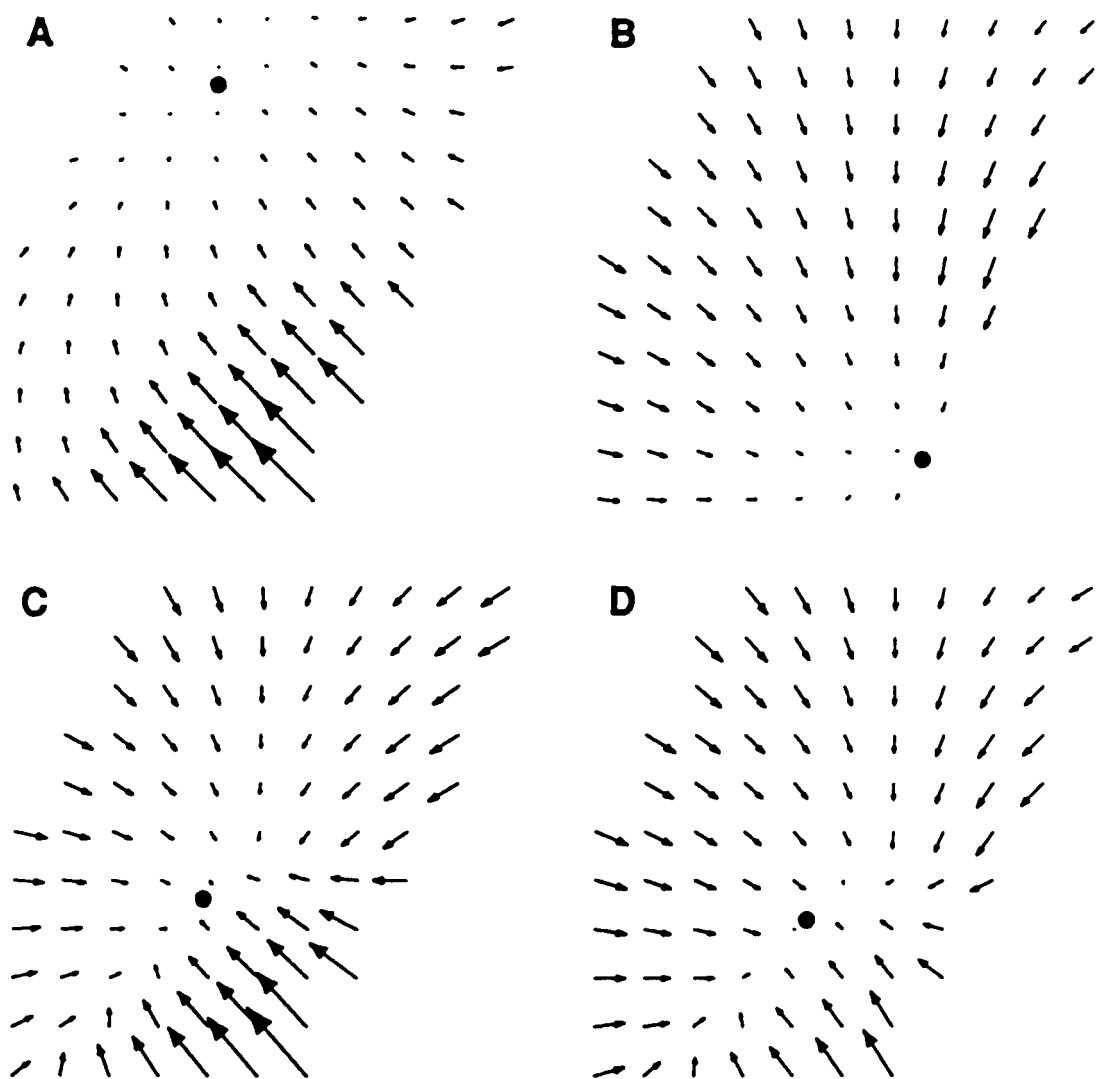

FIGURE 34.4 Combinations of multiple stimuli. (A) and (B) show the individual fields resulting from stimulation at two different sites in the premotor areas of the lumbar spinal cord. The equilibrium of field (A) is in extension, and (B) is in flexion. (C) The computed field $[AB]$ predicted by a simple vector-

ial summation of fields (A) and (B). (D) The actual field evoked by stimulation of (A) and (B) together. The equilibrium point is indicated by a filled circle. (From Bizzi, Mussa-Ivaldi, and Giszter, 1991.)

Force fields as modules of control

The results of microstimulation of the frog's spinal cord have indicated that the spinal premotor circuits are organized in a relatively small number of modules. From an anatomic point of view, each module establishes—presumably via propriospinal connections—a common drive to a set of agonist and antagonist muscles. From a functional point of view, each module generates a field of forces. This field can be regarded as an elementary unit of control because it determines univocally the force generated by the module in response to any externally imposed state of motion of the limb.

A limb's posture is encoded implicitly as a stable equilibrium point within this field. Equilibrium is defined as the point at which force vanishes. Stability is ensured by the module producing a force that pulls the limb back toward the equilibrium point in response to a displacement. This operation leads to a force field that converges toward the equilibrium point. Thus, a module implements a stable posture by generating a force field that converges to that posture. In addition, a module can generate movement by producing a force field that varies in time so that the equilibrium point shifts from an initial to a final position. This concept not only is consistent with the aforementioned equilibrium point hypothesis, but it also provides a more general theoretical

framework. Although the equilibrium point hypothesis specifies only the location of the equilibrium point and the local stiffness around this location, the force field specifies the pattern of forces across the entire workspace of a limb. This is an important feature that allows the control system to deal with the nonlinear properties of arm dynamics and to generate a class of behaviors that include the exertion of contact forces against objects in the environment.

Two major findings have emerged from the microstimulation experiments: (1) stimulation of several sites across the lumbar spinal cord produced only a few qualitatively distinct force fields, and (2) the force fields generated by spinal microstimulation added vectorially when two stimuli were applied simultaneously at two different spinal sites. These findings suggest the hypothesis that the motor system may create a variety of movements by the superposition of the force fields produced by a small set of independent spinal modules. The plausibility of this hypothesis has been tested in simulation studies by Mussa-Ivaldi and Giszter (1992) and Mussa-Ivaldi (1997).

The generation of movement by the combination of modules

In robotics (Brady et al., 1982), a desired trajectory is expressed as a temporal sequence of positions to be assumed by the limb. This sequence then is transformed by means of an inverse dynamics computation into a corresponding sequence of joint torques or muscle forces. The underlying assumption is that motor commands operate directly on the muscles and that muscles behave like ideal force generators. This assumption is quite plausible when dealing with conventional robots, whose motion controllers operate on nearly ideal force sources, such as torque motors. The amount of force generated by an ideal source does not depend on the position or the velocity at which it operates.

Our current understanding of muscle mechanics and of the circuits of the spinal cord offer a radically different scenario. Muscles are quite different from ideal force generators because their viscoelastic properties cause the force that they produce to depend on the muscle length and shortening velocity in addition to driving command. Furthermore, the microstimulation experiments and other neurophysiologic evidence indicate that most of the descending commands do not have access to individual muscles but rather to groups of muscles mediated by spinal interneurons. We formalize these notions by stating that the descending neural commands select and add vectorially the force fields generated by independent modules of control. In this new

computational scheme, the desired trajectory of the limb is not translated by the supraspinal circuits into a temporal sequence of force commands but instead into a set of commands that select and tune a corresponding set of modules of control.

Mathematically, this process may be expressed as follows. Let $D(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$ represent the passive nonlinear dynamics of the limb. The variables \mathbf{q} , $\dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$ are, respectively, the vectors of joint angles, angular velocities, and angular accelerations. The function $D(\bullet)$ is a nonlinear relation that transforms these kinematic variables into a corresponding vector of joint torques. The active force field generated by a spinal module, m , also may be represented as a nonlinear function of the joint angles and angular velocities and of time: $\phi_m(\mathbf{q}, \dot{\mathbf{q}}, t)$. The dependence of a module's force on position and velocity is a direct consequence of the viscoelastic properties of the muscles. The dependence on time is a consequence of the dynamics of muscle contraction and of the interactions among spinal neurons. The evidence that we have discussed previously suggests that the descending commands do not alter the form of these force fields. Instead, the descending commands operate by recruiting different modules in different amounts. In a first approximation, the recruitment of a module, m , by a central command may be represented as a (non-negative) scaling factor, c_m , that changes uniformly the amplitude of the forces without altering their direction.¹ Then, a system of K modules leads to a net force field:

$$\sum_{m=1} c_m \cdot \phi_m(\mathbf{q}, \dot{\mathbf{q}}, t)$$

The net dynamics of the limb and of the control system may be represented by the differential equation:

$$D(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}) = \sum_{m=1} c_m \cdot \phi_m(\mathbf{q}, \dot{\mathbf{q}}, t) \quad (2)$$

Given a particular set of selection coefficients and a specification of the initial position and velocity, this equation admits a unique trajectory $\hat{\mathbf{q}}(t)$ as its solution.

In this framework, the central command is represented by a K -dimensional vector of selection parameters, $\mathbf{c} = (c_1, c_2, \dots, c_K)$. This is quite different from the pattern of joint torques, which must be computed explicitly in the inverse dynamic methods.

The computational problem with a modular system is that of deriving the selection parameters that lead to the execution of a desired trajectory. This problem may be approached as one of function approximation: given a desired trajectory, find a set of selection coefficients that

minimize the error between the desired trajectory and the trajectory that results from the selection coefficients.

In a simulation study, Mussa-Ivaldi (1997) has shown that this approximation problem can be expressed as a problem of linear least-squares in the selection coefficients. Therefore, for any desired trajectory, a unique set of parameters that minimize the error measure can always be found.² Obviously this method does not guarantee that an arbitrary movement can be implemented with unlimited accuracy. The force fields produced by the module represent a constraint on the trajectories that may actually be generated by the control system.

Is it possible, given such a constraint, to reproduce the kinematic features of reaching arm movements? The simulation studies of Mussa-Ivaldi (1997) indeed show that by combining a small number of convergent force fields with stereotyped time dependency, it is possible to generate the intersegmental coordination that makes the hand move along a rectilinear path with a bell-shaped velocity profile. In these simulations, the force fields were divided in two classes: “step” fields and “pulse” fields. These two classes differed only by their dependence on time. The forces generated by the step fields started from zero amplitude and reached monotonically a plateau during the movement time. The forces generated by the pulse fields also started from zero amplitude, then they reached a peak value and returned to zero amplitude during the movement time. Models based on similar temporal patterns have been successful in dealing with the control of saccadic eye movements (Robinson, 1981). Figure 34.5 (see also color plate 21) illustrates a simulated arm movement produced by the combination of pulse and step fields. In addition to approximating the desired arm kinematics, this control system generates a temporal sequence of force fields with a moving equilibrium point, that is, a virtual trajectory thus reproducing the stability properties that are typical of observed reaching movements (Bizzi et al., 1984; Hogan, 1985).

Modules as a basis for representing movements: motor learning

Although spinal force fields offer a practical way to generate movement, they also provide the CNS with something equivalent to a movement's representation. This representation is similar geometrically to the representation of space by a set of Cartesian coordinates. In the latter case, we may take three directions—represented by three independent vectors—and then project any point in space along these directions. As a result, an arbitrary point in space is represented by three numbers, the co-

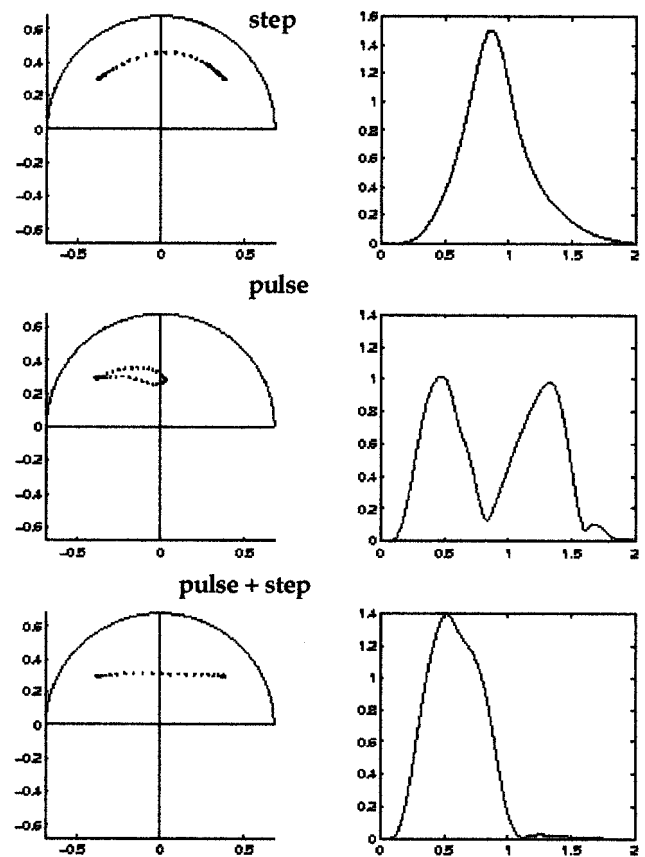

FIGURE 34.5 Simulation of arm movement by the combination of pulse and step fields. The three frames on the left side show the workspace of a two-joint planar arm. The shoulder joint is at the center of the coordinate system. Hand trajectories are shown as dotted curves, with the dots separated by equal sampling intervals. The panels on the right display the velocity profiles of the movements on the left. (Top) Movement resulting from the activation of a step field. The starting position is to the left of the shoulder, the target to the right. This field sets the equilibrium point on the target. (Middle) Movement resulting from the activation of a pulse field. The starting point is the same as for the step. As the field reaches the maximum intensity, the hand moves toward the right side. Then the field amplitude decreases, and the hand returns to the starting position. (Bottom) Movement resulting from the vectorial summation of the step and pulse fields of the top and middle panels. The pulse fields effectively correct the movement curvature produced by the step field (top panel). At the end of the movement, the pulse field ceases to be effective, and the final position is determined by the step field. The resulting movement is nearly rectilinear, and the velocity profile is unimodal. In this simulation, the parameters that modulate the amplitude of the pulse and step fields were chosen to approximate a straight-line movement from left to right with symmetric velocity profiles. Units: space (m), time (sec), velocity (m/sec).

ordinates x , y , and z . The movements of a limb can be considered “points” in an abstract geometrical space. In this abstract geometrical space, the force fields produced by a set of modules play a role equivalent to that of the

Cartesian axes, and the selection parameters that generate a particular movement may be regarded as generalized projections of this movement along the modules' fields.³ In this view, the representation of a trajectory—that is, the particular set of selection parameters that implement this trajectory—depend both on a limb's passive dynamics and on the set of fields generated by the modules.

If the dynamics change and the modules remain unchanged, then the representation of the movement must change accordingly. This is shown by the following argument. Suppose that a trajectory, $q(t)$, is represented by a selection vector $c = (c_1, c_2, \dots, c_K)$ for a limb with the dynamics of Equation (1). Now suppose that the limb dynamics are modified by an additional unexpected load, $E(q, \dot{q}, \ddot{q})$. Leaving the representation and the fields unchanged, we now have a new differential equation:

$$D(q, \dot{q}, \ddot{q}) + E(q, \dot{q}, \ddot{q}) = \sum_{m=1} c_m \cdot \phi_m(q, \dot{q}, t)$$

whose solution is a trajectory, $\tilde{q}(t)$, generally different from the original trajectory $q(t)$. The old selection vector has become a representation for $\tilde{q}(t)$. The old trajectory is recovered by changing the selection coefficients to a new set $c' = c + e$, with

$$E(q(t), \dot{q}(t), \ddot{q}(t)) = \sum_{m=1} e_m \cdot \phi_m(q(t), \dot{q}(t), t)$$

With these new coefficients, the new dynamics become equivalent to the old dynamics along the original trajectory.⁴ The modified coefficients c' are a new representation of the old movement $q(t)$ in the altered dynamics. This procedure for forming a new representation and for recovering the original movement is consistent with the empirical observation of after effects in load adaptation⁵ (Shadmehr and Mussa-Ivaldi, 1994).

Is it necessary for the motor system to modify a movement's representation each time the limb dynamics changes, or is there a way for restoring the previously existing representations? From a computational point of view, whenever a dynamic change is permanent—as when we undergo growth or damage—it would seem convenient for the CNS to have the ability to restore the previously learned motor skills (i.e., the previously learned movement representations) without needing to relearn them all. There currently is no strong experimental evidence to resolve this issue. However, the representation of motor primitives as force fields provides a theoretical insight. It may be

possible for the adaptive system to restore, at least partially, the motor representations that preexist a change in dynamics, and to do so, it is necessary to modify the modules and their force fields. A specific modification is obtained when we may express the coefficients $e = (e_1, e_2, \dots, e_K)$ as a linear transformation of the original coefficients $c = (c_1, c_2, \dots, c_K)$:

$$e = Wc$$

This transformation represents a coordinate transformation of the selection vector and may be implemented by a linear associative network. With a minimum of algebra one sees that

$$\begin{aligned} D(q, \dot{q}, \ddot{q}) + E(q, \dot{q}, \ddot{q}) &= \sum_{m=1} c'_m \cdot \phi_m(q, \dot{q}, t) \\ &= \sum_{m=1} (c_m + e_m) \cdot \phi_m(q, \dot{q}, t) \\ &= \sum_{m=1} c_m \cdot \bar{\phi}_m(q, \dot{q}, t) \end{aligned}$$

where the old fields ϕ_m have been replaced by the new fields

$$\bar{\phi}_m = \sum_{l=1} (I_{l,m} + W_{l,m}) \cdot \phi_l$$

This again is a coordinate transformation of the original fields, which may be implemented by a neural network intervening between the descending commands and the original fields. By means of this coordinate transformation, one obtains the important result that the movement representation—that is, the selection vector c —can be maintained invariant after a change in limb dynamics.

One may regard this form of invariance as the motor counterpart of the perceptual stability that allows the visual system to identify objects and faces in variable light conditions and from different viewpoints. As in the visual system, the possibility of constructing invariant representations within the motor system rests on the existence of independent primitives—the spinal force fields—that form a basis for constructing a variety of behaviors.

NOTES

1. This simplification is supported by the observation that variable intensities of stimulation in the frog's spinal cord resulted in changes of force field amplitude but not in changes of force directions (Giszter, Mussa-Ivaldi, and Bizzi, 1993).

2. This globally optimum solution is found by minimizing the error

$$\left\| \begin{matrix} D(\hat{q}(t), \dot{\hat{q}}(t), \ddot{\hat{q}}(t)) \\ c_m \phi_m(\hat{q}(t), \dot{\hat{q}}(t), t) \end{matrix} \right\|_{m=1}$$

over the desired trajectory, $\hat{q}(t)$. This is a quadratic expression in the selection coefficients. The global solution is obtained by solving for c_m the linear system of K equations

$$\int \phi_n(\hat{q}(t), \dot{\hat{q}}(t), t) \cdot D(\hat{q}(t), \dot{\hat{q}}(t), \ddot{\hat{q}}(t)) dt \\ \left[\int \phi_n(\hat{q}(t), \dot{\hat{q}}(t), t) \cdot \phi_m(\hat{q}(t), \dot{\hat{q}}(t), t) dt \right] c_m \\ m=1$$

where the dot operator indicates the scalar product. This system is guaranteed to have a solution if and only if the determinant of the field autocorrelation matrix

$$\Phi_{m,n} \equiv \int \phi_n(\hat{q}(t), \dot{\hat{q}}(t), t) \cdot \phi_m(\hat{q}(t), \dot{\hat{q}}(t), t) dt$$

does not vanish.

3. This is not just an analogy but a formal equivalence. In analytic geometry, a 3D vector r is represented as

$$r = x_1 \cdot \vec{e}_1 + x_2 \cdot \vec{e}_2 + x_3 \cdot \vec{e}_3 \quad (3)$$

where \vec{e}_1, \vec{e}_2 and \vec{e}_3 are three vectors forming a *basis* for 3D space and x_1, x_2 and x_3 are three numbers, the representation of r with respect to this basis. In the case of movement control, the expression

$$D(q(t), \dot{q}(t), \ddot{q}(t)) = c_1 \cdot \phi_1(q(t), \dot{q}(t), t) \\ + c_2 \cdot \phi_2(q(t), \dot{q}(t), t) \\ + \dots + c_K \cdot \phi_K(q(t), \dot{q}(t), t)$$

is identically satisfied if and only if the trajectory $q(t)$ is a solution of the differential equation (1). Like x_1, x_2 and x_3 , the selection coefficients c_i are real numbers that modulate the functions ϕ_i . Thus, the latter play the same role as the basis vectors in (2). The procedure to calculate the coefficients described in the previous footnote is formally equivalent to a projection operation.

4. Because if

$$D(q(t), \dot{q}(t), \ddot{q}(t)) = \sum_{m=1} c_m \cdot \phi_m(q(t), \dot{q}(t), t)$$

and

$$E(q(t), \dot{q}(t), \ddot{q}(t)) = \sum_{m=1} e_m \cdot \phi_m(q(t), \dot{q}(t), t)$$

are both identically satisfied, then also their sum

$$D(q(t), \dot{q}(t), \ddot{q}(t)) + E(q(t), \dot{q}(t), \ddot{q}(t)) \\ = (\sum_{m=1} c_m + \sum_{m=1} e_m) \cdot \phi_m(q(t), \dot{q}(t), t)$$

is identically satisfied.

5. If the load is removed after the new representation is formed, the dynamics becomes

$$D(q, \dot{q}, \ddot{q}) = \sum_{m=1} (c_m + e_m) \cdot \phi_m(q, \dot{q}, t)$$

that can be rewritten as

$$D(q, \dot{q}, \ddot{q}) = \sum_{m=1} e_m \cdot \phi_m(q, \dot{q}, t) \\ + \sum_{m=1} c_m \cdot \phi_m(q, \dot{q}, t)$$

Therefore, removing the load with the new representation corresponds approximately to applying the opposite load with the old representation.

35 Spatial Representations and Internal Models of Limb Dynamics in Motor Learning

CLAUDE GHEZ, JOHN W. KRAKAUER, ROBERT L. SAINBURG,
AND MARIA-FELICE GHILARDI

ABSTRACT In this chapter we propose that the planning of reaching movements depends on the learning of three internal representations and that visual and proprioceptive feedback play different roles in this process. Prior studies have shown that movements to visual targets are planned in a vectorial representation of space centered at the hand. Here we show that adaptation to gain changes, which require rescaling a visuomotor transformation, is more rapid than adaptation to rotations, which require rotating the frame of reference. Generalization differs between the two learning conditions. Subjects readily learn new scaling factors after training with a single target and use them to move accurately to targets at different distances and directions from the origin. With rotations, training with a single target allows them to aim movements accurately only if the target is in the same direction. However, they remain accurate in that direction when moving from different initial positions. It is inferred that training results in learning a directional axis that can be translated in the workspace. To learn a complete reference frame requires training to targets in at least 8 directions. Visual feedback is sufficient and proprioception is not necessary to learn new gains and rotations.

The planning of movement as a vector implies a second representation, that of hand position. The finding of systematic position-dependent directional biases indicates that proprioception alone is not sufficient for the origin of movement vectors to be specified with accuracy. Instead we suggest that visual information is necessary to calibrate the proprioceptive representation of hand position in space.

Straight and accurate movements also require learning the dynamic properties of the limb. This third representation is known as an internal model. We studied this process by examining how subjects adapt to a novel inertial load that changes the inertial interactions at the elbow. Training with a single target does not generalize to other directions; however, learning

can be applied to new positions in the workspace if the joint angle changes are the same. Thus, unlike learning a new spatial reference frame, new internal models of inertial dynamics are encoded in intrinsic coordinates. Changing the sources of sensory feedback shows that only proprioceptive feedback is necessary for this learning.

The differences in the rules for learning spatial transformations and inertial models suggest that the two processes are independent. This was confirmed by showing that consolidation of newly learned spatial reference frames and new inertial models are independent and interference remains restricted to each form of learning. We therefore suggest that separate working memory buffers are used in the two forms of learning.

It is widely accepted that the nervous system represents and plans reaching movements in extrinsic space: Despite variable joint motions, hand movements aimed to targets throughout peripersonal space remain straight and have stereotyped bell-shaped velocity profiles (Morasso, 1981). Both the velocity and acceleration profiles scale with movement extent (Atkeson and Hollerbach, 1985), even if target distance is unpredictable (Ghez, 1979; Gordon, Ghilardi, and Ghez, 1994). The straightness and linear scaling of early trajectory variables to the distance of the target show that the nervous system controls movement through feedforward mechanisms.

Detailed analyses of trajectory errors indicate further that hand movements are planned vectorially as extents and directions in a hand-centered coordinate system (Ghez et al., 1997; Ghez et al., 1990; Gordon, Ghilardi, and Ghez, 1994; Vindras and Viviani, 1998). These results agree with those from a study of single-cell recordings in primates by Georgopoulos and colleagues, which revealed populations of neurons in primary motor cortex that encode movement direction itself (Georgopoulos, Schwartz, and Kettner, 1986). The vectorial space in which intended movements are coded requires a known origin, that is, the initial hand position, and its relationship to other points in visual space. Visuospatial and

hand-centered vectorial maps can differ in terms of scaling or in reference frame depending on the task. Learning new spatial maps is therefore necessary if movements are to remain accurate.

To displace the hand in space along an intended trajectory, extent and direction need to be recoded in intrinsic coordinates to specify the appropriate muscle forces and joint torques (Flanders, Helms Tillery, and Soechting, 1992). Consistent with this, Kalaska and co-workers have identified populations of neurons in primary motor cortex that encode movement direction and joint motion successively (Scott and Kalaska, 1997). The transformation from extrinsic to intrinsic coordinates must take account of the complex mechanical effects of gravity, inertia, and intersegmental interactions (Hollerbach and Flash, 1982; Hoy and Zernicke, 1985; Hoy and Zernicke, 1986; Hoy, Zernicke, and Smith, 1985). Moreover, biomechanical conditions change with fatigue and other time varying factors. It is generally believed that to perform the transformation from extrinsic to intrinsic coordinates the dynamic properties of the limb, which are represented as an internal model by the nervous system, must be learned (Shadmehr and Mussa-Ivaldi, 1994; Ghez, 1979; Ghez et al., 1990; Ghez and Sainburg, 1995; Gordon, Ghilardi, and Ghez, 1995; Sainburg, Ghez, and Kalakanis, 1999). Although concurrent visual and proprioceptive feedback are critical in calibrating internal models of limb dynamics (Ghez, Gordon, and Ghilardi, 1995; Sainburg and Ghez, 1995), the role of proprioception in learning new dynamic models is not known.

In the first section of this chapter, we examine the roles of visual and proprioceptive feedback in adapting to changes in the gain and direction of visual feedback information and to changes in initial position of the hand. In the second section, we examine the learning of new models of inertial dynamics and the roles of proprioceptive and visual feedback in this. Finally, in the third section, we show that learning and consolidation of new spatial transformations and new inertial dynamics are independent.

Learning new spatial transformations

REMAPPING AND ROTATING REFERENCE FRAMES: ROLES OF VISUAL FEEDBACK Movement planning in a hand-centered vectorial space suggests that errors in extent and direction should be computed and processed separately. To determine whether this is the case, we studied the time course and the effects of changes in visual feedback as subjects adapted to changes in gain and to rotations in hand path displays around the starting position of the hand on a computer monitor. The values for

the gain change and the rotation were chosen to equate the linear error (distance from target to movement end point) of the predicted unadapted movement and presumably its salience. Subjects made out-and-back movements of their hand on a horizontal surface at shoulder level. Targets were displayed on the screen with a cursor indicating the position of their hand while an opaque shield prevented subjects from seeing their arm and hand. After a block of 60 to 90 trials, the motions of the screen cursor were changed unexpectedly. As can be seen in figure 35.1, after an increase in gain to 1.5:1, the first movements were overshoot by approximately 150%; when the hand path display was rotated counterclockwise 30°, movements were deviated by 30° in the same direction. Errors in extent and direction decreased rapidly over the first 5 to 10 movements and more slowly thereafter. In both cases, the decay in error was fit by a double exponential function. Subjects use errors detected with each movement to adjust either the extent or direction of the next movement by a given proportion of the error. The double exponential fit could reflect the use of two different strategies over time. In an initial period, when the systematic source of the error is most readily distinguishable from random variability, successive adjustments are large. Later, when systematic errors have become smaller and more difficult to distinguish from variable errors, a different adaptive strategy is chosen.

Time course of learning Adaptation to changes in gain is more rapid than adaptation to rotations (Pine et al., 1996). This is apparent comparing the initial slopes of the fitted lines in figure 35.1. Additionally, the systematic extent errors produced by the gain change are fully corrected after about 60 movements while with rotation, movements remain significantly deviated even after 90 movements (figure 35.1, top). Since the initial linear error was the same for both perturbations, the more rapid adaptation to the gain change does not result from differences in magnitudes of the errors induced by the perturbation.

Increasing the number of targets influences the time course of adaptation differently for gain and rotation. Adaptation to a new gain is more rapid and errors reach baseline sooner when the number of targets is increased from 1 to 8. In contrast, adaptation to a rotation is slower with 8 targets than with a single target (Krakauer et al., 1997).

The more rapid rate of adaptation to imposed gain changes when moving to multiple targets can be understood by assuming that errors are held temporarily in working memory. Movements to several target distances will then more readily reveal their common origin as scaling errors. The question arises, however, why the

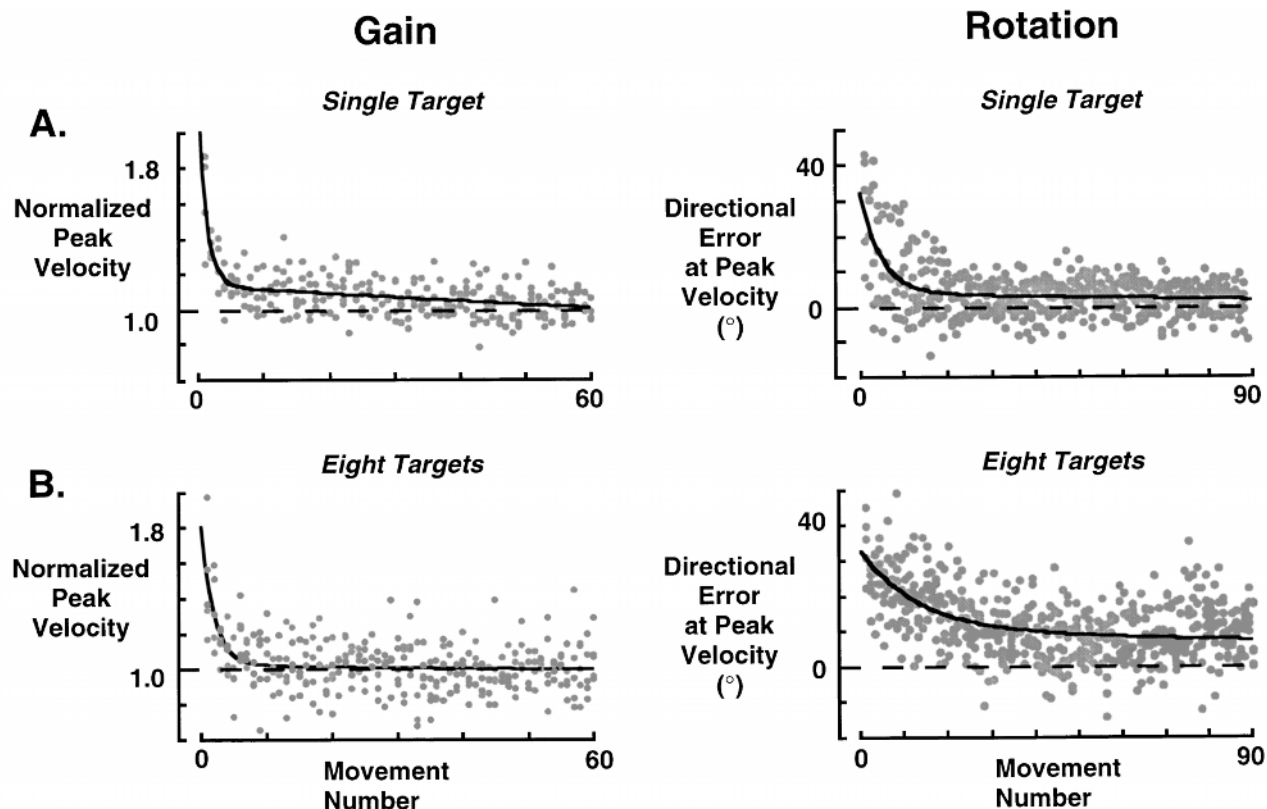

FIGURE 35.1 Time course of learning new gains and rotations. (A) Learning of the new gain (1.5) is measured as the scaling of the peak velocity to the target extent. Peak velocity was normalized by dividing it by target extent. Data are fitted

same improvement with multiple targets does not occur with rotation. One explanation might be that errors resulting from gain changes would be improved by rescaling the same pattern of motor neuron activation regardless of the position of the hand in the workspace or the direction of movement. Adjusting for a rotated reference frame may be more difficult. This is because movements in different directions are produced by different muscle patterns and joint rotations. Also the changes in joint rotation appropriate to counter a given directional error are different from those in the original reference frame. Therefore, it may be necessary for all directions to be sampled in order to derive the rule underlying the error. This suggests that adaptation to new gains generalizes across target distances, whereas adaptation to rotations is local.

Generalization of learning To demonstrate differences in generalization of learning gain changes and rotations, we trained subjects to move rapidly to a single target and back and changed the gain or direction of visual feedback. We then examined the errors they made when reaching for targets at different extents or directions without visual feedback.

by double exponential functions. (B) Learning of the 30° counterclockwise rotation was measured by the progressive reduction in the directional error at peak velocity.

The data in figure 35.2A show that learning the appropriate extents of movements made to near or to far targets in either of two directions generalizes across target distances and directions. With rotation, however, directional errors increase rapidly as the angle separating the test target from the training target increases (figure 35.2B). The slope of this decline becomes less with two and four training directions. With eight training directions, movements to intermediate targets are as accurate as those in the trained direction (Krakauer, Pine, and Ghez, 1996).

These results demonstrate that although visual feedback enables subjects to rapidly rescale vectorial representations of extrinsic space, learning a rotated reference frame centered on the hand is a more lengthy process and requires targets in several directions. The question of whether learning to move the hand in a single direction reflects a single stimulus-response association or the learning of a more general spatial transformation is considered later in this chapter.

LEARNING HAND POSITION IN VISUAL SPACE: ROLES OF VISUAL AND PROPRIOCEPTIVE INFORMATION In principle, the position of the hand in space could be computed from proprioception and knowledge of segment

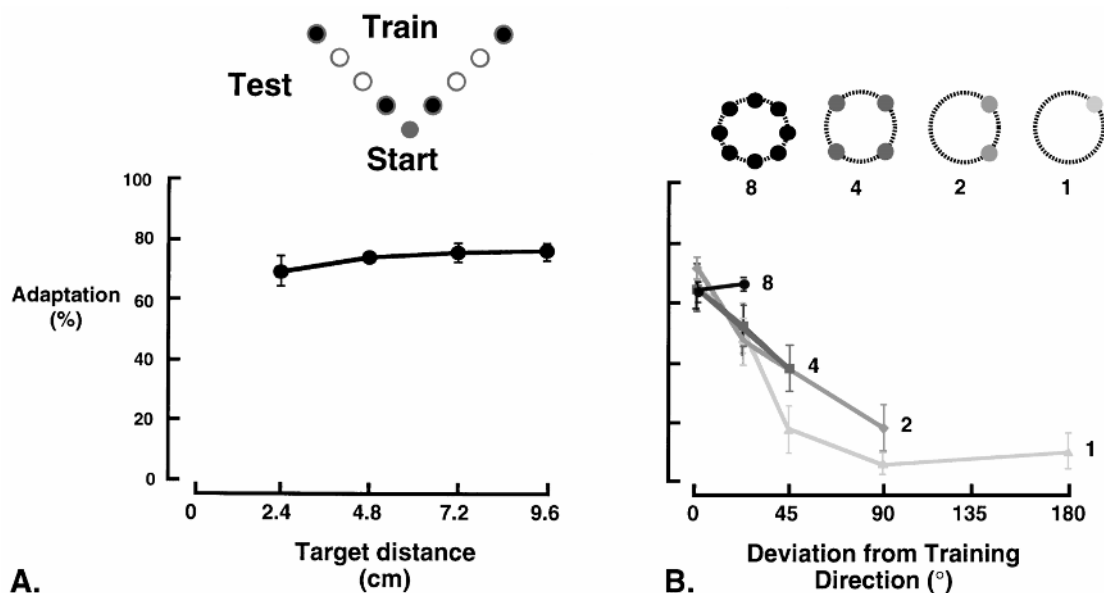

FIGURE 35.2 Generalization of learning after adaptation to gain changes and rotations in hand path displays. (A) Separate groups of subjects were trained, using visual feedback, to move to one or the other of the four black targets shown in the inset. They were then tested without feedback to all eight targets (gray circles). The degree of adaptation is a percentage ratio of the peak velocity in the control and test conditions divided by the gain change (1:1.5). No difference is present in the scaling of peak velocity between the trained and untrained directions indicating complete generalization. (B) As in (A), subjects

learned either 1, 2, 4, or 8 targets (*inset*) and were tested to 10 others (1 at 22.5° on either side of the trained direction plus the 8 directions shown in the inset labeled 8). The degree of adaptation is a percentage ratio of the directional error at peak velocity to the imposed rotation (30° counterclockwise). Individual points are averages across subjects for targets on both sides of the trained direction. For target separations greater than 45°, adaptation decays rapidly as target direction deviates from the trained direction.

lengths. However, this seems unlikely. First, the relationship of muscle length or joint angle to the discharge of muscle (Houk and Rymer, 1981; Matthews, 1981b; Matthews and Stein, 1969) is linear only over limited ranges of static positions. Thus, changes in lengths or angles produce different changes in neural activity for different initial conditions. Second, judgments of segment lengths, needed to compute hand position, can be unreliable or biased. Therefore, it is not surprising that estimates of hand position drift over time (Wann and Ibrahim, 1992).

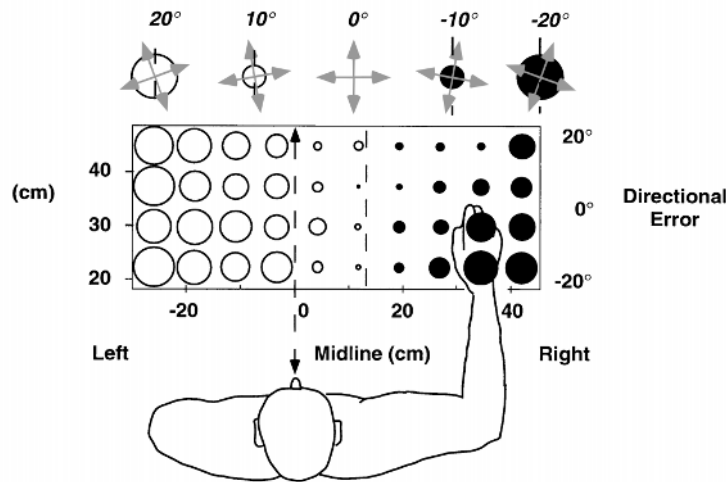

The inadequacy of proprioception alone in motor planning is also demonstrated by the consistent directional biases that occur when subjects reach for visual targets but cannot see their hands before movement (figure 35.3A). These biases increase as the initial position of the hand deviates from its usual location near a forward egocentric axis (Ghilardi, Gordon, and Ghez, 1995; Pine et al., 1998) and are present to the same degree when subjects simply are given verbal instructions to point in a given direction relative to their body.

These position-dependent biases disappear, however, if subjects can see their hand together with the targets directly in the same workspace. These biases could have resulted if, during the each block of trials, the represen-

tation of either hand or target location had drifted towards the location in which motor tasks are most frequently performed. Indeed, the precision and accuracy of spatial judgments is influenced by such central tendency biases (Poulton, 1975). Simple dynamic simulations (Pine et al., 1998) support the idea that when the hand is not visible, the brain relies on a remembered location of hand position that systematically underestimates the distance from its usual position by a given percentage.

If the specification of movement direction were based on inaccurately remembered hand positions, extensive training at a single location might be expected to abolish preexisting directional biases. Additionally, if the representation of hand position is biased by recent experience, new errors should be present at different initial hand positions but show the same position dependence as before training. As can be seen in figure 35.3B, the directional bias of movements made without visual feedback from a lateral starting point disappear when subjects are trained to move to the same targets with the hand continuously visible. However, when movements are made in other positions, new directional biases occur but vary with hand position in

A. Mean Directional Error

B. Mean directional errors before and after training with visual feedback

FIGURE 35.3 Position dependent directional biases. Subjects sat in front of a horizontal tablet and made reaching movements to a circular array of 12 targets shown on a vertical computer screen. Vision of the arm was obstructed by a shield. (A) Subjects ($N=3$) moved to a circular array of 12 targets without visual feedback after their hand was moved passively to the positions indicated by the circles. The diagram shows that mean directional error (across target directions) for each position varies with the position of their hand relative to the body midline. Biases are clockwise in regions to the left and counter-

clockwise of the right of an error free region extending forward from the body midline. The degree of bias is shown by the rotated “compass points” and the diameters of the circles. (B) Training with visual feedback in one location eliminates the directional bias present previously in that hand position (gray rectangle) but introduces biases throughout the rest of the workspace. These new biases increase with the mediolateral distance of the hand from the trained location. The three limb configurations are as shown in the schematic drawing.

the same way as before training: The two sets of points parallel each other in figure 35.3B.

These results add further support to the conclusion that the continuous flow of proprioceptive information during successive movements is not adequate to specify the origin of individual movement vectors. Instead, we suggest that vision of the hand and limb is necessary to calibrate these proprioceptive signals.

Learning new musculoskeletal dynamics

To displace the hand in space, the nervous system must also transform the intended direction and extent into feedforward control signals distributed to motor neurons and muscles. For the resulting movement trajectory to conform to the one that was intended, feedforward commands need to anticipate the effects of

both environmental forces and of forces arising within the musculoskeletal system itself. Internal forces include ones produced by muscles and by the inertial resistance. In linked mechanical systems such as the arm, dynamic interactions that occur among limb segments produce large time-varying torques at each joint. These depend critically on joint and hand velocities and, more importantly, on angular accelerations occurring during movement. Learning an internal model of these dynamic properties of the musculoskeletal system is essential to transform intended actions into mechanical displacement (Goodbody and Wolpert, 1998; Imamizu, Uno, and Kawato, 1995; Jordan, 1996; Lackner and Dizio, 1994; Sainburg, Ghez, and Kalakanis, 1999; Sainburg et al., 1995; Shadmehr and Mussa-Ivaldi, 1994).

It recently has been demonstrated that normal individuals can develop and store new internal models of both Coriolis forces (Lackner and Dizio, 1994) and of velocity-dependent force fields acting on the hand (Shadmehr and Mussa-Ivaldi, 1994; Shadmehr, Mussa-Ivaldi, and Bizzi, 1993): When the forces are removed unexpectedly, subjects show dramatic hand path curvatures that mirror the directions and magnitudes of the forces imposed during learning (“after-effects”).

Studies of deafferented patients, who lack any sensation of joint motion, have shown that proprioceptive feedback is essential to generate or update internal models of limb inertia and intersegmental dynamics (Ghez, Gordon, and Ghilardi, 1995; Ghez et al., 1990; Ghez and Sainburg, 1995; Gordon, Ghilardi, and Ghez, 1990; Gordon, Ghilardi, and Ghez, 1995; Sainburg et al., 1995; Sainburg, Poizner, and Ghez, 1993; Virji-Babul et al., 1997). In fact, muscle spindles and other mechanoreceptors do provide the nervous system with feedback signals that reflect velocities and accelerations of changes in muscle length and joint angles. Patients lacking proprioception because of the degeneration of large diameter afferent axons make large errors in movement amplitude that vary with the inertial configuration of the arm. They also are unable to reverse direction sharply in particular directions. These reversal errors have been found to reflect inadequate control of intersegmental forces which in the patients account entirely for the actual joint motions that take place during movement. Both direction and reversal errors, however, are reduced markedly when patients can see their limb before each movement. This improvement persists for a few minutes after vision is removed again (Ghez, Gordon, and Ghilardi, 1995; Ghez and Sainburg, 1995; Sainburg et al., 1995). Thus, patients can substitute visual for proprioceptive feedback to recalibrate an internal representation of limb dynamic properties. Nevertheless,

even with vision, deafferented patients cannot achieve full control of unconstrained multijoint movements in 3-D space (Sainburg, Poizner, and Ghez, 1993; Rothwell et al., 1982).

CONTROL OF INTERSEGMENTAL DYNAMICS: DIFFERING EFFECTS OF FEEDBACK IN CORRECTING ONGOING MOVEMENTS AND IN LEARNING NEW INTERNAL MODELS The mechanisms used to control intersegmental dynamics of the arm can be studied in both intact and deafferented subjects by altering the relationships between joint motions and torques. The experimental procedure is illustrated in figure 35.4A. The center of mass of the distal limb segment was displaced effectively by attaching a 1-kg load either medially or laterally to the longitudinal axis of the forearm. The subject’s task was to make a single overlapping out-and-back motion of the hand to trace a target line rapidly and accurately.

After adaptation to the medial load placement, the load was switched unexpectedly to the lateral position before movement onset, once every four to eight movements (“surprise lateral” condition in figure 35.4). Figure 35.4B illustrates the effect of this change in intersegmental dynamics on the hand trajectory: Just before the switch, the hand path consists of two nearly straight segments lying over the target line. In the surprise trial, however, the initial direction of movement remains straight but deviates clockwise away from the target and does not reverse direction sharply. This early clockwise direction error results from increased elbow extension, whereas the rounding of the trajectory during the movement reversals results from desynchronization of elbow and shoulder joint motions (Sainburg, Ghez, and Kalakanis, 1999).

The changes in elbow and shoulder rotations that produce the hand path deviations can be attributed to feedforward control calibrated to the intersegmental dynamics of the previously adapted condition: This is demonstrated with a simple forward simulation in figure 35.4B (left). The muscle torque profiles calculated from an adapted medial trial were applied to an ideal open-loop controller with inertial properties corresponding to the lateral mass condition. This computation estimated what would have happened if the subject had used the torques needed to control the medial mass accurately throughout the “surprise lateral” trial. The simulation can be seen to predict the initial direction errors accurately; however, the simulated reversals were curved less broadly than the actual ones. This indicates that although the early part of the trajectory resulted exclusively from feedforward processes, with time, feedback signals adjust the trajectory on line. Across subjects, this feedback degraded the sharpness of movement reversals in comparison with ones pro-

FIGURE 35.4 Errors in hand and joint trajectories when moving lateral loads. (A) Experimental set-up. The subject's arm was supported on air sleds on a horizontal glass surface, and the shoulder was stabilized. Hand position was visible to the subject as a screen cursor between and after movement. Joint angles were computed from potentiometers at the elbow and shoulder. A 1-kg load was placed either 25 cm lateral or medial to the hand, displacing the center of mass of the distal segment as indicated by the arrow. The major mechanical effect of this change of the center of mass of the distal limb segment was to increase the magnitude of the interaction torques produced at the elbow joint by motions at the shoulder. Changes

in inertial interactions at the shoulder were balanced by the minor changes in total limb inertia. Middle: Hand paths from the last trial of each adaptation session (left and right columns) and from a typical "surprise" trial in a single subject. Bottom: Elbow and shoulder joint angles corresponding to the trials above. (B) Typical adapted medial (left) and surprise lateral (right) trials are shown in black. The muscle torques computed from trained medial trial were used to simulate a pure after-effect uncontaminated by on-line correction. This simulation shows the effect of these torques had the mass not been displaced.

duced by the simulated feedforward controller acting alone. Nevertheless, the final position of the hand was achieved much more accurately in the actual than the simulated trajectory.

The ability of the subjects to return to the starting position despite large trajectory errors suggests that movement endpoints are determined by a mechanism that is distinct from the one responsible for the trajectory itself. Feldman and Bizzi (Bizzi, Polit, and Morasso, 1976; Feldman, 1974; Mussa-Ivaldi, Hogan, and Bizzi, 1985; Polit and Bizzi, 1979) described equilibrium control models that exploit the viscoelastic properties of the musculoskeletal system (mediated by muscle properties alone or including reflexes) through simultaneous activation of antagonistic muscle groups

to specify a specific equilibrium position in either joint or hand space. In these models the desired final position is attained independently of the trajectory, which may vary depending on task dynamics. Hirayama and coworkers (Hirayama and Jordan, 1993) incorporated a similar positional control mechanism into a two-phase computational model of trajectory control. In that model, initial trajectory features reflected a feedforward mechanism, whereas final position was achieved using a postural controller that used visual feedback to specify levels of stationary motor commands to groups of muscles.

Thus, we conclude that the dynamics of rapid reaching movements are controlled by three distinct mechanisms that operate successively. First, movements are

controlled through feedforward mechanisms that are adapted to existing mechanical conditions. Second, as sensory feedback becomes available during movements, corrections are made. Such corrections may be maladaptive if the dynamic properties of the limb are altered. Learning allows such corrections to become appropriate. Third, the final position of the hand is also controlled through postural mechanisms that can be implemented once the limb is no longer moving rapidly at the end of movement.

INTERNAL MODELS OF INTERSEGMENTAL INTERACTIONS ARE ENCODED IN INTRINSIC COORDINATES The results shown in figure 35.4 demonstrate that with practice moving the hand to a single target and back, subjects can adjust both feedforward and feedback mechanisms to control hand trajectory. Does learning to move a given extent in a single direction with a new inertial configuration allow subjects to do so accurately when moving from different starting positions and in different directions? In examining this, we first determined whether accuracy obtained with practice moving a medial or a lateral load to a single target transfers to movements in other directions from the same origin. This was not the case; direction and reversal errors increased as the target direction deviated from the one used for training. Beyond 45° on either side of the trained direction, there no longer was any evidence of this prior practice. Thus, learning shows only limited generalization to new directions from the same position (Gandolfo, Mussa-Ivaldi, and Bizzi, 1996; Sainburg and Ghez, 1995; Sainburg, Ghez, and Kalakanis, 1999). This lack of generalization would be expected if during training subjects learned the dynamic interactions that occur during a specific set of joint motions. Alternatively, subjects might simply have learned to move their hand a particular distance and direction in extrinsic space. To distinguish between these possibilities, subjects were trained to move their hand accurately with the lateral load out and back to a single target from a specific location in the workspace (again without visual feedback). We then examined the accuracy of movements made with the same load but starting from a different position in the workspace presented occasionally as surprise trials (figure 35.5A) and to two new targets. The two targets were selected to require either the same joint excursions or the same extent and direction of hand movement as during training. Figure 35.5B shows that movements made to the target that required the same joint excursions as that of training (“joint space”) were substantially more accurate than those made to the other target (“hand space”).

These results indicate that learning of inertial dynamics is represented in an intrinsic coordinate system re-

lated to muscle actions or proprioceptive signals, rather than in visual coordinates. This is consistent with our earlier observations, based on similar experimental paradigms, that proprioception plays a critical role in the control interaction forces (Sainburg et al., 1995).

LOCAL LEARNING OF MOVEMENT DIRECTION IN A ROTATED VISUAL FIELD IS ENCODED IN EXTRINSIC SPACE We have seen earlier that when subjects adapt to a rotated display by training to a single target, learning does not generalize to other directions. This is similar to what occurs when moving to a single target with a new inertial configuration of the arm. Thus, adaptation to a rotated hand path display but with a single target in a given direction also may reflect the learning of a more general rule represented either in extrinsic or in intrinsic coordinates.

As previously, we addressed this question by training subjects to move out and back from a single spatial location to a given target with vision of the hand and arm occluded; however, present subjects had continuous visual feedback on the computer screen. After a block of control trials, the displays of hand paths were rotated counterclockwise by 60°. Subjects then were tested without feedback as they moved to the same locations shown on the screen but from a different initial position and arm configuration (figure 35.6A). Figure 35.6B shows that in the displaced position, directional errors clustered around those predicted if subjects had encoded prior learning in extrinsic space rather than the one that would be appropriate if learning was represented in joint coordinates. Figure 35.6C shows the large differences in joint angle changes in trained and test positions in one of the six subjects. Thus, with a rotated display and a single target direction, subjects depend on the directional errors they observe visually on the computer screen to learn to move along a directional axis that can be translated to other locations in the workspace. Unlike in the learning of new inertial dynamics, proprioceptive information representing errors in intrinsic space does not play a significant role (see discussion).

Consolidation and interference in learning rotated reference frames

It is generally accepted that for the brain to learn cognitive and motor tasks, sensory events, and motor commands occurring in the course of task performance are stored in working memory. It has been suggested that the neural space in short or working memory is limited and that individual events or associations compete for this space (Baddeley, 1992; Ballard, Hayhoe, and Pelz, 1995).

FIGURE 35.5 Inertial dynamics are learned in intrinsic space. (A) Schematic of the experimental paradigm to examine transfer of learning across the workspace. Subjects practiced moving with the lateral mass to the single 128° , 10-cm target on the left of the workspace using visual displays of their hand paths. The shoulder and elbow angles corresponding to the beginning of the target were 55° and 90° , respectively. After 100 trials of practice, occasional trials required subjects to move from

a second position to one of the targets on the right of the workspace without visual feedback. One of these targets matched the direction and length of trained target exactly, and the other target required the same angular displacements of the joints as the trained target and therefore was different in direction and length. (B) Ensemble averaged hand paths from a single subject who trained with the lateral mass position to the 128° , 10-cm line in the left of workspace.

Over time, however, items in working memory are transferred to new locations and distributed in multiple brain regions for long-term storage. It is known that if subjects are given a task to relearn hours, days, and weeks after initial practice, learning is more rapid and complete, a process called *consolidation*.

Shadmehr and coworkers discovered that consolidation also occurs in motor learning, in a task requiring subjects to make straight reaching movements to visual targets in a rotating viscous force field (Brashers-Krug, Shadmehr, and Bizzi, 1996). The rate of learning improved when subjects receive two successive sessions of practice separated by one or more days. However, if subjects were given the task of learning a force field rotating in the opposite direction, consolidation failed to occur. This *interference* was greatest at 5 minutes and decreased over the course of 6 to 24 hours, when consolidation was complete (Brashers-Krug, Shadmehr, and Bizzi, 1996;

Shadmehr and Brashers-Krug, 1997; Shadmehr and Holcomb, 1997).

ADAPTING TO DISPLAY ROTATIONS IS UNAFFECTED BY INTERVENING OR CONCURRENT LEARNING OF NOVEL INERTIAL DYNAMICS The differences in coordinate systems and in sensory feedback channels used to learn new visuomotor transformations and new inertial dynamics described in earlier sections suggests that the two forms of learning might take place independently of each other. If this were true, interference with consolidation would be restricted to each process.

To answer this question, subjects were trained to reach for targets in eight directions with an imposed 30° counterclockwise rotation of hand paths displayed on the screen (as in figure 35.1B, right). Subjects then were retested 24 hours later, and the rates of learning during the two days were compared. Four groups of subjects were

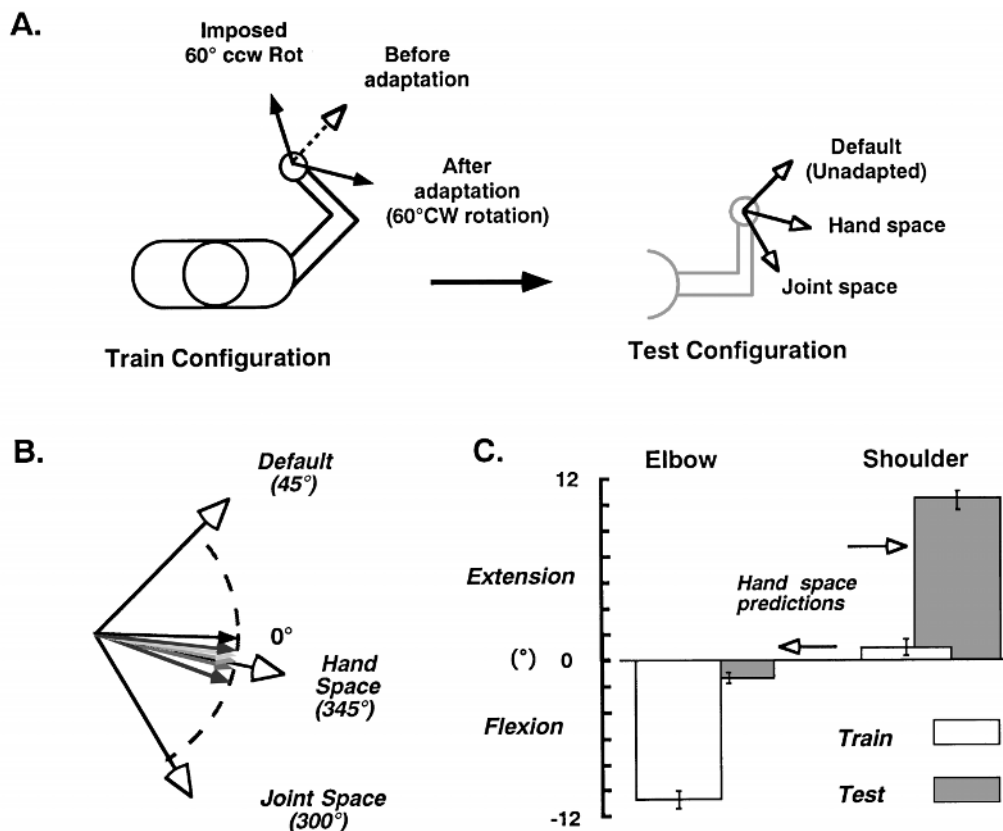

FIGURE 35.6 A rotated direction of hand movement is learned in extrinsic space. (A) Schematic of experimental paradigm to examine transfer of learning across the workspace. *Training:* Subjects faced a vertical display and were instructed to make planar reaching movements to a screen target at the 45° position. Cursor feedback was rotated 60° counterclockwise requiring adaptation for accuracy to be achieved. The actual hand directions before and after adaptation are indicated by the arrows in the training configuration: shoulder at 45°, elbow at 90°. *Testing:* Subjects had their trunk moved while maintaining the same origin of the hand; this resulted in a new arm configuration: shoulder at 90°, elbow at 90°. They were then tested in the novel configuration, without feedback, to the same screen target in the presence of the 60° rotation. The empty arrows in the test configuration indicate the predicted hand directions if adaptation were absent, if learn-

ing were in joint space, or if learning were of a trajectory in hand space. (B) A polar plot of mean hand movement direction for six subjects in the novel configuration after adaptation in the training configuration. Each subject is represented by a single arrow. The larger gray arrows represent predicted performance as described in (A). All six subjects were distributed around the predicted performance if they were to have adapted in hand space. (C) A bar chart of mean elbow and shoulder angle changes for a single subject in the training and testing configurations. The angle changes were computed using the subject's limb segment lengths and handpaths. Note that the joint angle changes differ markedly for the two configurations, suggesting that the subject is not learning in joint space. The arrows represent the expected joint angle changes if the subject were to adapt perfectly in hand space.

studied (figure 35.7). A first group was not given any additional practice between days (figure 35.7A) and represented the control group. A second group learned to move a laterally displaced load 5 minutes after the rotation (figure 35.7B). A third group did so concurrently as they learned the rotation (figure 35.7C, dual task). Finally, a fourth group (figure 35.7D) learned a rotation in the opposite direction (30° clockwise) 5 minutes after the initial 30° counterclockwise rotation. Subjects had visual feedback (screen cursor) at all times.

As can be noted in figure 35.7A there is clear evidence of consolidation in learning the rotated visuomo-

tor transformation: The initial rate of learning was significantly greater on day 2, and the residual error at the end of the training session was significantly less on day 2 than on day 1. These indices of consolidation were unaffected when subjects learned to move a lateral load 5 minutes after the rotation (figure 35.7B) or concurrently with it (figure 35.7C). Conversely, there was no significant difference between the rates of learning a 30° counterclockwise rotation on day 1 and day 2 when subjects learned a rotation in the opposite direction immediately after the first training session (figure 35.7D). Thus, although there is consolidation in the learning of a

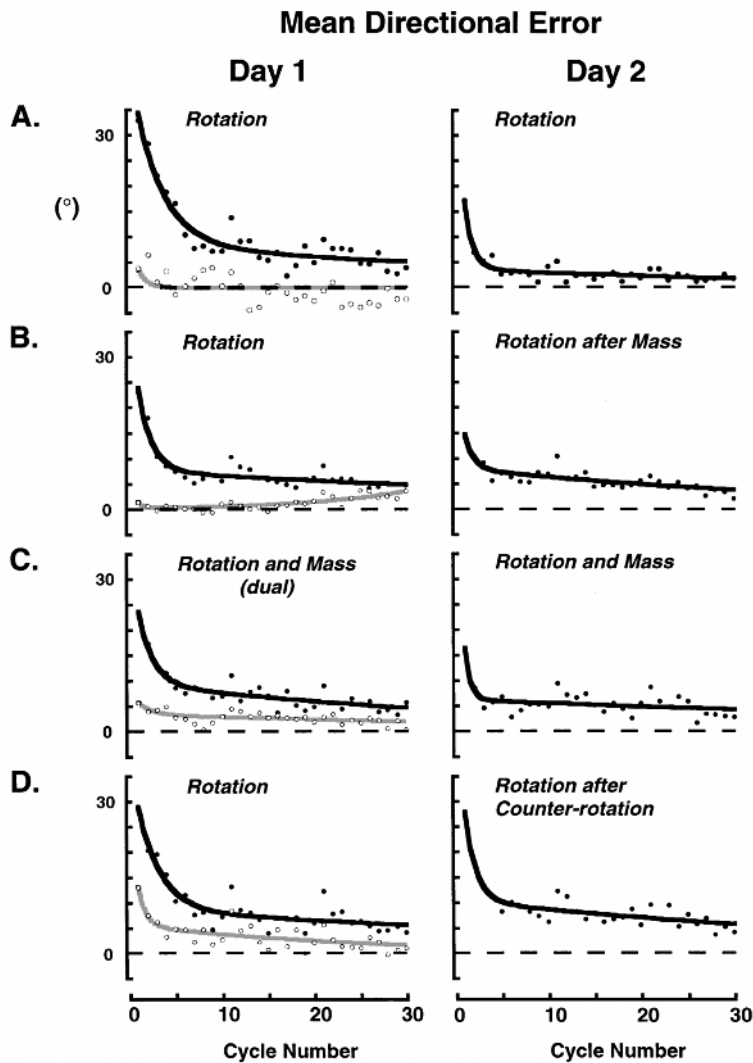

FIGURE 35.7 Consolidation and interference in learning a new reference frame. For each condition the mean directional error per cycle (cycles represent movements to the 8 target directions) is plotted against cycle number during the training block. Points are means across subjects; lines are fitted to the

points by double exponential function. The empty circles represent the single familiarization trial before rotations or load changes. The black circles represent training trials. Differences between conditions were evaluated by comparing the means of the first two and the last two cycles using a factorial ANOVA.

spatial rotation and interference when subjects learn an opposite rotation, there is no interference when subjects learn new internal models of inertial dynamics. The opposite is also true: Consolidation in the learning of the same change in limb dynamics is unaffected by learning a 30° counterclockwise rotation, either at the same time or 5 minutes later (Krakauer, Ghilardi, and Ghez, 1998).

Discussion

The observations presented here describe three internal representations that are necessary to plan fast and accurate reaching movements. Each is subject to adaptive learning but uses different feedback signals and obeys different rules. The first representation encodes the spa-

tial features of the task in a vectorial space where target location is represented in terms of extent and direction from the initial hand position. Visual errors detected in successive movements operate to rescale and reorient this spatial map. We have proposed a second representation to locate the hand in peripersonal space. This proprioceptive map requires frequent recalibration by visual or other sensory signals. Finally, the third is a representation of critical biomechanical characteristics of the limb. This representation is needed to transform intended movement vectors into appropriate muscle forces or joint torques. Proprioceptive feedback is critical in establishing such new internal models of inertial dynamics. The terminal portions of hand and joint trajectories are consistent with the idea that movement endpoints may

also be determined redundantly by specifying the intended final hand position in space. This planned final position could depend on the same proprioceptive map of task space as the origin of the intended movement vector.

The rules underlying adaptation to altered gains and rotations indicate that errors in extent and direction are used differently in rescaling and in reorienting visuospatial maps of movement vectors. Rescaling is relatively rapid and generalizes throughout the workspace in an approximately linear fashion. Errors in movement direction adjust the orientation of the reference frame; however, this form of learning is local: When directional errors are experienced moving to a single direction, subjects learn a directional axis that can translate in the workspace. For subjects to learn a complete reference frame in a horizontal space centered at the hand, 8 or more equally spaced target directions are necessary. In this case, however, the time course of learning is greatly prolonged. It appears that visual information alone is sufficient to rescale and to reorient spatial reference frames for motor planning. Unpublished data in two patients with large-fiber sensory neuropathy (C. Ghez, J. Gordon, and M. F. Ghilardi, unpublished studies of patients M.A. and I.W.) indicates that learning new scaling factors and spatial reference axes does not require proprioceptive information. Similarly, mirror drawing was found to be unimpaired in a third patient (G.L. in Blouin, Bard, Teasdale et al., 1993).

In contrast to learning gains and rotations, learning new models of limb dynamics depends critically on proprioception. Observations in one deafferented patient indicate that visual feedback alone cannot provide the necessary information. Indeed, the patient was unable to reduce the inertial errors by monitoring either the cursor on the screen or her arm in the workspace (Virji-Babul et al., 1997; N. Virji-Babul et al., in preparation).

The differences in coordinate systems and in sensory signals required suggest that learning new spatial representations depends on different neural channels and different sites for memory storage. While learning a rotated reference frame interferes with the consolidation of a previously learned rotation in the opposite direction, learning a new model of limb dynamics does not. Similarly, the rate at which a new internal model is learned and its consolidation in memory are unaffected by learning a new spatial reference frame. Finally, the rate at which subjects adapt to rotations or to new inertial interactions is unchanged when they learn both concurrently. Thus, learning new representations of extrinsic space and learning new internal models of inertial dynamics involve different neural systems and separate working memory buffers.

Many studies have demonstrated that working memory buffers (Baddeley, 1992; Ballard, Hayhoe, and Pelz, 1995) have a limited capacity. This could be the major determinant of the higher rate of learning and generalization in learning new scaling factors than in learning rotated reference frames or inertial models. Prochazka and his colleagues have pointed out that the amount of proprioceptive information generated during each movement is very large (Prochazka, 1996). Consequently, limited memory capacity should present a particular challenge for acquiring skill in tasks where the motions at many joints must be controlled precisely or in skills, such as golf, in which objects with unusual inertial configurations are to be rapidly displaced.

On the basis of the observations summarized in the section *Remapping and Rotating Reference Frames: Roles of Visual Feedback*, we proposed that movement accuracy also requires learning a map of extrinsic space represented as joint angles. The special importance of static as opposed to dynamic signals in generating such models is suggested by the more linear coding of static than of dynamic information by muscle spindles (Houk and Rymer, 1981; Matthews, 1981a). Over some range, the same hand position could be specified by scaling the ratio of muscle activations as proposed by equilibrium theories (Feldman, 1974; Bizzi et al., 1984). Nevertheless, such proprioceptive maps of space are apt to be rather coarse, given the time-dependent fluctuations in receptor responses. The specification of an entire trajectory as a large series of equilibrium trajectories seems implausible because of the large nonlinear changes in the contractile forces of muscles during length changes.

Our observations are consistent with computational models that can transform information about intended actions into neural signals that specify torques at joints. Such models propose the existence of inverse and forward internal models that adjust feedforward as well as feedback controllers (Jordan and Rumelhart, 1990; Wolpert, Ghahramani, and Jordan, 1995). With repeated trials, the parameters of these models would be adjusted by comparing expected sensory input, available as corollary discharge signals (Bell, 1982; Matthews, 1982) and sensory feedback acquired in the course of movement. The psychophysical observations presented here suggest that separate sensory motor representations, along with distinct working memory buffers supporting them, do exist in the nervous system.

ACKNOWLEDGMENTS The authors are indebted to Zachary Pine for reading earlier versions of this chapter and for conducting experiments that directly led to the ones presented here. We thank Dr. Dimitrios Kalakanis for scholarly comments and assistance in editing portions of this chapter. We are also grateful to Hao Huang and Walton B. Comer, who devel-

oped software for experiment control and data analysis, and to Antony Hacking for expert assistance with illustrations. We are grateful to Professor Jonathan Cole for allowing us to study visuospatial learning in patient I.W. Supported by NS22715 and NS01961.

36 Programming to Look and Reach in the Posterior Parietal Cortex

R. A. ANDERSEN, A. P. BATISTA, L. H. SNYDER, C. A. BUNEO, AND Y. E. COHEN

ABSTRACT Classically, the posterior parietal cortex (PPC) has been believed to be an association sensory area responsible for attention and spatial awareness. Over the past few years, however, a new idea has emerged that this area also analyzes sensory information for the purpose of planning actions. Experiments from the authors' laboratory have shown that the PPC has an anatomic map with respect to intentions. The PPC is an "association" cortex in the sense that it must combine different sensory modalities, which are coded in different coordinate frames, within this map for action plans. Interestingly, two different areas of the PPC, one involved with moving the eyes (the lateral intraparietal [LIP] area) and another involved with moving the arms (the parietal reach region [PRR]), both appear to represent the goals for movements using the same set of rules, even though the eventual outcome of their activities are for different behaviors. In both areas, individual neurons code spatial locations using a common reference frame, that is, with respect to the eye, but these responses also are gain-modulated by eye and body position signals. At the population level, this mechanism allows these areas to code concurrently a goal for movement in multiple coordinate frames (eye, head, body, and world). Depending on how this group of cells is sampled by other areas of the brain, different coordinate transformations can be accomplished by this same population of neurons.

The posterior parietal cortex generally is believed to be a high-order sensory region that contributes to spatial awareness. The phenomenon of "neglect," which results after lesions to this area, manifests as a deficit in attending to objects in the affected visual field or in shifting attention and has been used as a prime example of a sensory attention role for PPC (Critchley, 1953; Andersen, 1987, for review). However, another syndrome also common with PPC lesions is apraxia. This deficit is neither sensory, because subjects still have normal visual and other sensory functions, nor motor, because the patients are not paralyzed. However, they seem unable to form the "plan" or "idea" for a movement. Thus, this deficit is interposed between sensation and action and appears to result from a disruption in the early stages of movement planning (Critchley, 1953, for review). In recent years, several studies in humans and monkeys point

to a newly appreciated role of the PPC in programming actions, and more specifically, in transforming sensory signals into plans for motor behaviors (Mountcastle et al., 1975; Gnadt and Andersen, 1988; Goodale and Milner, 1992; Rizzolatti, Riggio, and Sheliga, 1994; Andersen, 1995; Mazzoni et al., 1996b; Sakata et al., 1997; Snyder, Batista, and Andersen, 1997).

A new and emerging view of the PPC is that it contains an anatomic map of intentions (Andersen et al., 1997; Snyder, Batista, and Andersen, 1997) (figure 36.1). Included in this map for movement planning is area LIP, which appears to be specialized for making saccades. A region medial and posterior to area LIP, PRR, is specialized for planning reach movements. This area likely includes the dorsal aspect of the parieto-occipital (PO) area and the medial intraparietal (MIP) area. A third task-specific area is the anterior intraparietal (AIP) area, located just rostral to area LIP, which appears to be specialized for grasping (Sakata et al., 1997). Finally, within the fundus of the intraparietal sulcus is an area with somatosensory receptive fields around the mouth and head and visual receptive fields that in many cases prefer stimuli moving toward the animal's mouth and head (Duhamel, Colby, and Goldberg, 1998). This ventral intraparietal (VIP) area may be specialized for "grasping" with the mouth.

In this review, we cover studies revealing the role of PPC in intention. Also of interest are studies examining the coordinate frame in which space is represented in area LIP and PRR. This work was designed to determine how different modalities that are represented originally in different coordinate frames are brought together in the PPC. We also discuss how communication may be achieved between these different areas, which are highly interconnected anatomically (Andersen et al., 1990; Blatt, Andersen, and Stoner, 1990), and how these areas might incorporate common processing strategies for the orchestration of complex behaviors requiring hand-eye coordination. As we will see, area LIP and PRR appear to use a common mechanism for representing visually and auditorily cued spatial locations. The resulting representation has the computationally powerful

Anatomical Organization for Actions in the Posterior Parietal Cortex

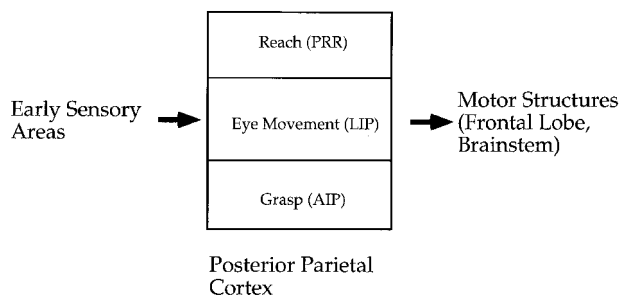

FIGURE 36.1 The posterior parietal cortex contains separate areas specialized for reach movements (area PRR), saccades (area LIP), and grasping (area AIP).

feature that it is distributed and can be read out by other areas of the brain as several different coordinate frames, for example, eye-, head-, body-, or even world-centered. Finally, we review research that finds that the representations of space in both area LIP and PRR are updated across eye movements for the remembered locations of targets for movement.

Intentions to saccade and reach

There is a considerable amount of suggestive evidence that the PPC has an intentional role, but it has been very difficult to design experiments that dissociate intention-related activity from activity related to attention. This difficulty arises from the fact that monkeys (and humans) attend to locations where they plan to make movements. In a recent study, we designed a task specifically to isolate intention-related activity (Snyder, Batista, and Andersen, 1997). We reasoned that activity in the PPC should be indifferent to the type of movement planned by the animal if it is only related to attention. Thus, if the monkey planned a reach or a saccade to the stimulus at the same location, there should be little or no difference in activity if it is primarily dependent on attention. However, if the activity depends strongly on the movement the monkey plans, then this activity would be related to the animal's intention.

Animals were trained to memorize the location of briefly flashed visual stimuli in an otherwise dark room and to plan either an eye or an arm movement to the cued location, the type of movement being instructed by the color of the flashed stimulus. Figure 36.2 demonstrates our typical result—that the activity in the memory period depended largely on the type of movement the animal planned. Approximately two thirds of PPC neurons showed a significant response in the memory pe-

riod for only one of the two movement plans. The remaining one third of the cells responded to both plans. However, approximately one half of the cells responding for both movements appeared to be forming a default plan for a particular type of movement, as shown in an additional control and thus also were intention related. We proposed that these cells were coding “covert” plans for movement. An example of one of these covert planning cells is shown in figure 36.3. This cell had activity during the memory period regardless of whether the animal planned a reach or a saccade into its receptive field. In the control experiment, we had the animal perform a two-movement task, in which he planned and

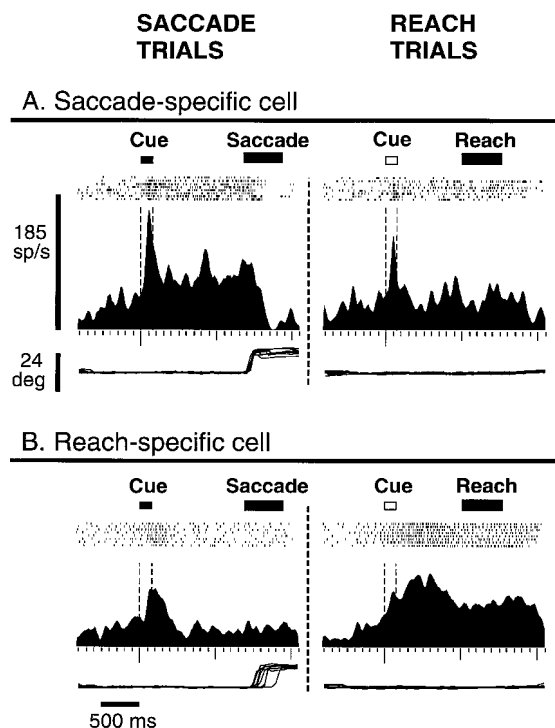

FIGURE 36.2 Responses of two intention-specific neurons in the delayed-saccade (left) and delayed-reach (right) tasks. Each panel shows timing of peripheral flash (Cue: red flashes indicated by filled bars, green flashes by open bars) and response (Saccade or Reach); eight rows of rasters corresponding to every third action potential recorded during each of eight trials; a spike density histogram of neuronal activity, generated by convolution with a triangular kernel aligned on cue presentation, with cue onset and offset indicated by dashed lines; and eight overlaid traces showing vertical eye position. Neuronal responses in the cue interval (50 ms before to 150 ms after cue offset) were nonspecific. However, during the delay interval (150–600 ms), firing depended specifically on motor intent. (A) A cell showing elevated delay period firing before a saccade (left) but not before a reach (right). For illustration purposes, data for this cell were collected using a fixed delay interval. (B) A second cell showing reach rather than saccade specificity during the delay interval. (Reprinted from Snyder, Batista, and Andersen, 1997.)

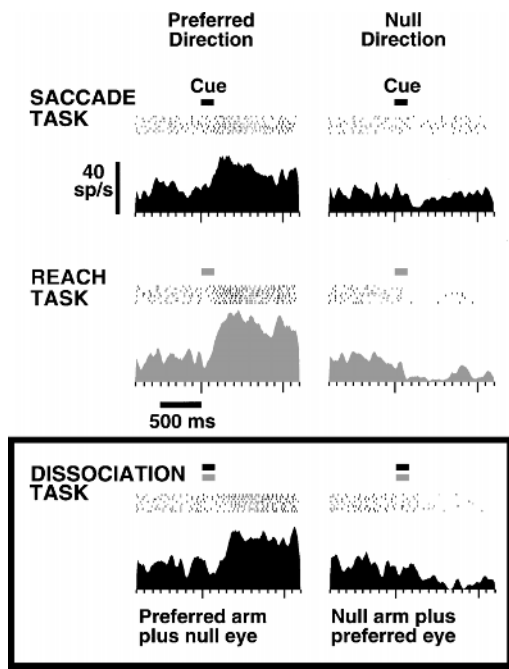

FIGURE 36.3 An intention-specific neuron whose motor specificity was revealed by the dissociation task. Delay activity was greater before movements toward the receptive field (Preferred Direction) compared with away (Null Direction) in both delayed saccade (top row) and reach (middle row) tasks. Thus, in single-movement tasks, the neuron appears to code remembered target location independent of motor intent. However, motor specificity was revealed in the dissociation task (bottom row). Firing was vigorous before a preferred reach combined with a null saccade (bottom left) but nearly absent before a preferred saccade plus null reach (bottom right). Thus, when both a reach and a saccade were planned, delay activity reflected the intended reach and not the intended saccade. Panel formats are similar to figure 36.1. Every other action potential is indicated by one raster mark. (Reprinted from Snyder, Batista, and Andersen, 1997.)

made eye and reach movements simultaneously in opposite directions. The bottom panels of figure 36.3 illustrate that when the animal planned an arm movement into the receptive field but an eye movement outside the receptive field, the cell was active, but when it planned the eye movement into the receptive field and the arm movement outside of the receptive field, the cell was not active. Thus, it would appear that the animal was making a “default” plan to reach that was not executed. Because half of the cells responding to both plans demonstrated a covert preference for either saccades or reaches, overall 84% of the PPC cells tested had activity during the memory period specifying the intent of the animal.

The intended movement activity was anatomically segregated depending on whether it was related to plans for saccades or reach. Perhaps not surprisingly, eye movement planning activity was found predominantly

in area LIP. This finding is very consistent with previous research, which has indicated that area LIP can be considered the “posterior eye field” for the processing of saccadic eye movements (Andersen, Brothie, and Mazzoni, 1992). Area LIP cells have presaccadic bursts of activity (Barash et al., 1991); saccade deficits result after lesions in area LIP (Lynch and McLaren, 1989; Li, Mazzoni, and Andersen, 1999); there are strong anatomic projections from area LIP to other saccade centers, such as the superior colliculus, frontal eye field, and dorsal-lateral pons (Lynch, Graybiel, and Lobeck, 1985; Asanuma, Andersen, and Cowan, 1985; Blatt, Andersen, and Stoner, 1990; Andersen et al., 1990); and electrical microstimulation of area LIP evokes saccades without other body movements (Thier and Andersen, 1996, 1998). The reach selective responses were found medial and posterior to area LIP, in a band of cortex that likely includes areas MIP to PO. We referred to this functionally defined region of the PPC as the parietal reach region (PRR).

The focus of attention and the planning of eye movements are linked tightly, so it could be argued that the selectivity in area LIP is due to the fact that animals attend to where they plan to saccade but not to where they plan to reach, and the differential activity reflects this difference in attention (Colby and Goldberg, 1999). However, this line of reasoning would require PRR neurons also to be most active when eye movements are planned in their receptive fields; instead, we see the reverse phenomena, with activity being greatest when reaches are planned into their receptive fields. Moreover, in the following experiments, attention was maintained the same and the animals were asked to change their movement plans. As we see, when attention is identical across trials, the activity of PPC neurons changes dramatically depending on the animals’ plans.

Changing movement plans without changing the locus of attention

A direct prediction from the aforementioned conclusions is that activity should shift between areas LIP and PRR when monkeys change their movement plans. We have tested this prediction with the paradigm shown in figure 36.4 (Snyder, Batista, and Andersen, 1998). The experiment began in a similar manner to the aforementioned one, with a flash of light instructing a particular type of movement to the location of the flash inside the receptive field of a cell. However, in the later period of some of the trials, this plan either was changed by a second flash of a different color or was reaffirmed by a flash of the same color. The animals did not know what the subsequent flash

Single flash trials:

Double flash trials:

FIGURE 36.4 Time course of eight single- and double-flash trials. The experiment was designed to force the animal to attend to the spatial location and color of both flashes. A 150-ms flash appeared 750 ms after fixation began. Red and green flashes instructed saccades and reaches, respectively. On half of the trials, a second flash occurred 750 ms later at the same location as the first, sometimes instructing a change in the motor plan but never shifting spatial attention. Fixation light offset, 2.5 s after the first flash, signaled the animal to perform the most recently instructed movement. For one animal, double-flash trials also occurred for the null direction (not shown). (Reprinted from Snyder, Batista, and Andersen, 1998.)

would instruct, and because these second flashes always appeared at the same location as the first flashes, the monkeys' attention was the same whether the plan was changed or reaffirmed.

The response was related strongly to the animals' intentions. Figure 36.5 shows the activity of a reach neuron (figure 36.5A) and a saccade neuron (figure 36.5B) when the monkey changes plans from a reach to a saccade and vice versa. The activity of the neurons is much stronger when the preferred movement is cued. In the reach cell illustrated in figure 36.5A, the activity also is much higher during the first and second delays when the monkey is planning a reach instead of a saccade. These dramatic plan-related changes in neural response during the delay are taking place without the animal emitting any behavior at all. The animal is simply changing his intentions during the delay period.

The plan dependency across the population of PRR cells can be seen in figure 36.6A. The response to the first flash is larger when it is green and therefore is instructing a reach. This reach-planning activity remains high during the first delay period. The middle panel shows the responses to a second, green flash instructing a reach, segregated into two plots, depending on whether this second flash reaffirmed or changed the

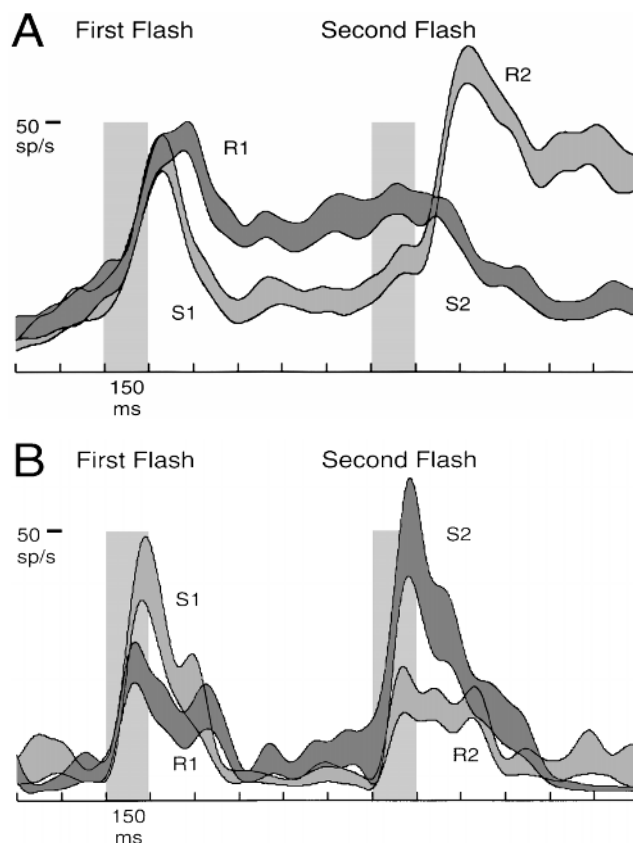

FIGURE 36.5 (A) Intention-selective responses of a parietal reach region (PRR) neuron to changes in motor plan, from a saccade to a reach (light trace) or from a reach to a saccade (dark trace). Sustained activity resulting from an instruction to plan a reach (R1) was abolished when a second flash changed the plan to a saccade (S2). An initial instruction to plan a saccade elicited only a transient response (S1), but when the plan was changed to a reach, activity increased (R2). Instruction to plan a reach elicited a larger response when countermmanding a previous plan than when presented alone (R2 transient and sustained responses are larger than R1 responses). The reverse was true for a flash instructing a saccade (S2 transient less than S1 transient). Each ribbon is the mean response of 8 to 12 trials ± 1 standard error of the mean (SE). Shading indicates the time of one 150-ms flash. Data were smoothed before plotting (121-point digital low-pass filter, transition band 20–32 Hz). (Reprinted from Snyder, Batista, and Andersen, 1998.)

plan. In this instance, the response to the identical green flash, under identical attention conditions, was much stronger if the animals were required to change their plans. Thus, it can be concluded that a large com-

ponent of the flash-triggered activity actually reflects a shift in plans. The plots on the right show that this change-in-plan-specific activity is not a result of the novelty. These plots show the responses to the second flash when it is red and instructing an eye movement. These responses were small for the nonpreferred plan, regardless of whether it was a change or reaffirmation of the previous plan. Thus, the enhanced response to the flashes was present only when there was a change of plan to the preferred plan. The same result was found for LIP neurons, but saccades were the preferred plan.

Coding the next planned movement in the lateral intraparietal area and the parietal reach region

Using a memory double saccade paradigm, we found that most of area LIP neurons code the next planned eye movement (Mazzoni et al., 1996b). As shown in figure 36.7D, for a representative neuron, when the second target of the planned sequence of movements fell within the receptive field of the LIP cell but the animal was planning the first eye movement outside of the receptive field, this cell showed only a brief response to the stimulus and was not active in the memory period. However, if the same target fell within the receptive field of the cell and it was the target for the first eye movement, then the cell was active during the memory period (figure 36.7C). This result is typical of most (77%) LIP neurons. There also was a minority of cells with activity for the second target during the memory phase, and these cells appear to hold the memory of the location of the second target.

We recently performed a similar double-movement experiment in the PRR but required the monkey to plan two reaches instead of two saccades (Batista et al., 1998). In this task, we first cued the monkey to a location for a reach within the receptive field of the neuron. However, during the delay period, if we flashed a second target outside the receptive field of the cell, the animal was required to make the reach first to that target. At the end of the delay, the animal reached to this second target and another delay period began in which he then planned a movement to the first flashed target location. At the end of this second delay, the animal made a second limb movement to the remembered location of the first target. We found that, similar to LIP cells, PRR cells ceased firing to the remembered location of the first reach target when the monkey was planning an arm movement to the location of the second target, outside the receptive field of the cell. Moreover, we found when we reversed the sequence of targets so that the second target and first reach were in the receptive field, the activity still was always only present when the next

planned movement was into the receptive field. Thus, PRR shares another similarity with area LIP, with PRR neurons coding the next planned movement in double-movement tasks. This result adds further support for the idea that a large component of both PRR and LIP activity reflects the animals' plans or intentions for movement.

The coordinate frame of the lateral intraparietal area for visual stimuli

Lateral intraparietal neurons have receptive fields much like neurons in other visual areas, which are in the coordinates of the retina or eye—that is, the locations in space that activate these cells move with the eyes. However, we also have found that the activity of these cells is modulated by eye position and head position (Andersen et al., 1990; Brotchie et al., 1995; Snyder, Grieve, et al., 1998). Neural network simulations show that these “gain field” effects can serve as the basis for a distributed coding in other coordinate frames besides an eye-centered frame (Zipser and Andersen, 1988). Thus, for instance, neurons in another part of the brain that receive inputs from area LIP could construct receptive fields in head-centered coordinates by exploiting the eye position gain fields. Likewise, the combination of eye and head position gains can be used to construct body-centered representations (figures 36.8 and 36.9).

Coordinate frame for the lateral intraparietal area for auditory stimuli

Area LIP is considered an extrastriate visual area. It is at approximately the same level as area V4 (Andersen et al., 1990; Blatt, Andersen, and Stoner, 1990) when considered within the hierarchy of visual areas based on feedforward and feedback patterns of corticocortical connections (Maunsell and van Essen, 1983). Thus, it is imbedded deeply in the extrastriate visual cortex and occupies a position relatively early (i.e., close to V1) in the visual pathway. This is reflected in the brisk responses of area LIP to visual stimuli, even when the animal is ignoring the stimulus (Linden, Grunewald, and Andersen, 1997) or is anesthetized (Blatt, Andersen, and Stoner, 1990).

LIP neurons usually do not respond to auditory stimuli. However, because area LIP plays a major role in processing saccades and because monkeys obviously can make saccades to auditory stimuli, we hypothesized that LIP neurons would be active when the monkey used auditory stimuli for the purpose of making eye movements. This is in fact the case (Mazzoni et al.,

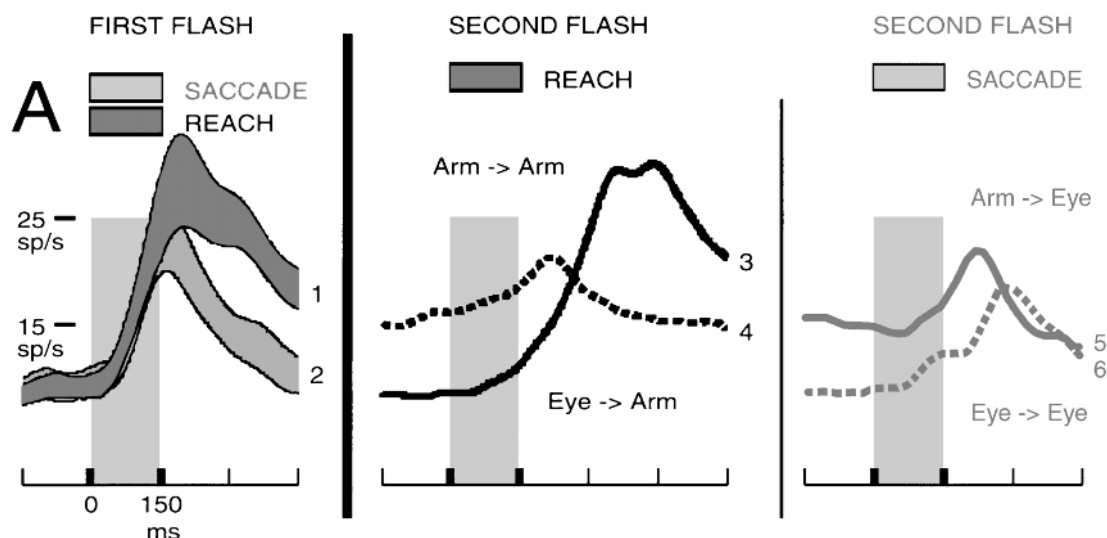

FIGURE 36.6 Population data from the parietal reach region (PRR) ([A] average of 17 cells). Responses to the first (left panel) and second (right and middle panels) flashes, instructing either a saccade (light) or a reach (dark) are shown. Second flashes could instruct a preferred (middle) or nonpreferred (right) movement, and this instruction could countermand (traces 3 and 5) or affirm (traces 4 and 6) the original instruction. Response to a preferred countermanding flash was larger

than to a preferred affirming flash (3 vs. 4) and comparable with the response to a preferred first flash (1). For nonpreferred movements, countermanding and affirming flashes elicited similar comparatively small responses (5 vs. 6). Format as in figure 36.5, except that SE was calculated across cells rather than across trials (left). (Reprinted from Snyder, Batista, and Andersen, 1998.)

1996a; Grunewald, Linden, and Andersen, 1997). We also have determined the reference frame of these auditory triggered responses in a memory-guided eye movement task. In very early levels of the brain dedicated to determining the spatial location of auditory stimuli, cells have auditory receptive fields in head-centered coordinates. These head-centered fields are constructed using interaural time, intensity, and spectral cues. Conversely, in area LIP, we found only 33% of the cells had fields in head-centered coordinates whereas a surprising 44% had fields that were in eye-centered coordinates (Stricanne, Andersen, and Mazzoni, 1996). The remaining 23% of the cells had fields that were intermediate between these two coordinate frames. One parsimonious interpretation of these results is that area LIP is responsible for converting head-centered auditory signals into eye-centered coordinates. The neurons with auditory responses in area LIP typically also have eye position gain fields. These gain effects could provide the mechanism for converting auditory signals from a head-centered to an eye-centered representation.

These findings have two important implications. First, the fact that area LIP only responds to auditory stimuli when they are of oculomotor significance to the animal presents a very different view of multimodal integration than is commonly held. It suggests that area LIP usually is a default visual area, involved in transforming visual stimuli into eye movement plans. How-

ever, when auditory stimuli are deemed to be targets for saccades, then LIP becomes active. Second, when auditory signals are relayed to area LIP, they are transformed into the eye-centered reference frame of this area. This result suggests that vision provides the basic map for spatial location within area LIP. As we will see, these two ideas also can be extended to PRR. In fact, for many forms of extrapersonal spatial analysis and behavior, space may be represented in eye coordinates and other modalities may be brought into the eye-centered representation when multimodal integration is required. This idea certainly makes good ecological sense for vision and audition because audition can give us the general location of a stimulus but only our high-resolution vision can locate precisely a target of interest. This concept may explain the ventriloquist effect, in which visual stimuli tend to dictate the perceived spatial location of the auditory stimuli. In this illusion, if we see someone's lips moving but the speech source is from a different location in space, we nonetheless perceive the sound as coming from the moving lips.

Reference frame for the parietal reach region

We recently examined the reference frame for reach-planning activity in PRR. One possibility is that the reach activity is in the coordinates of the limb, coding the motor error for a limb movement. Alternatively,

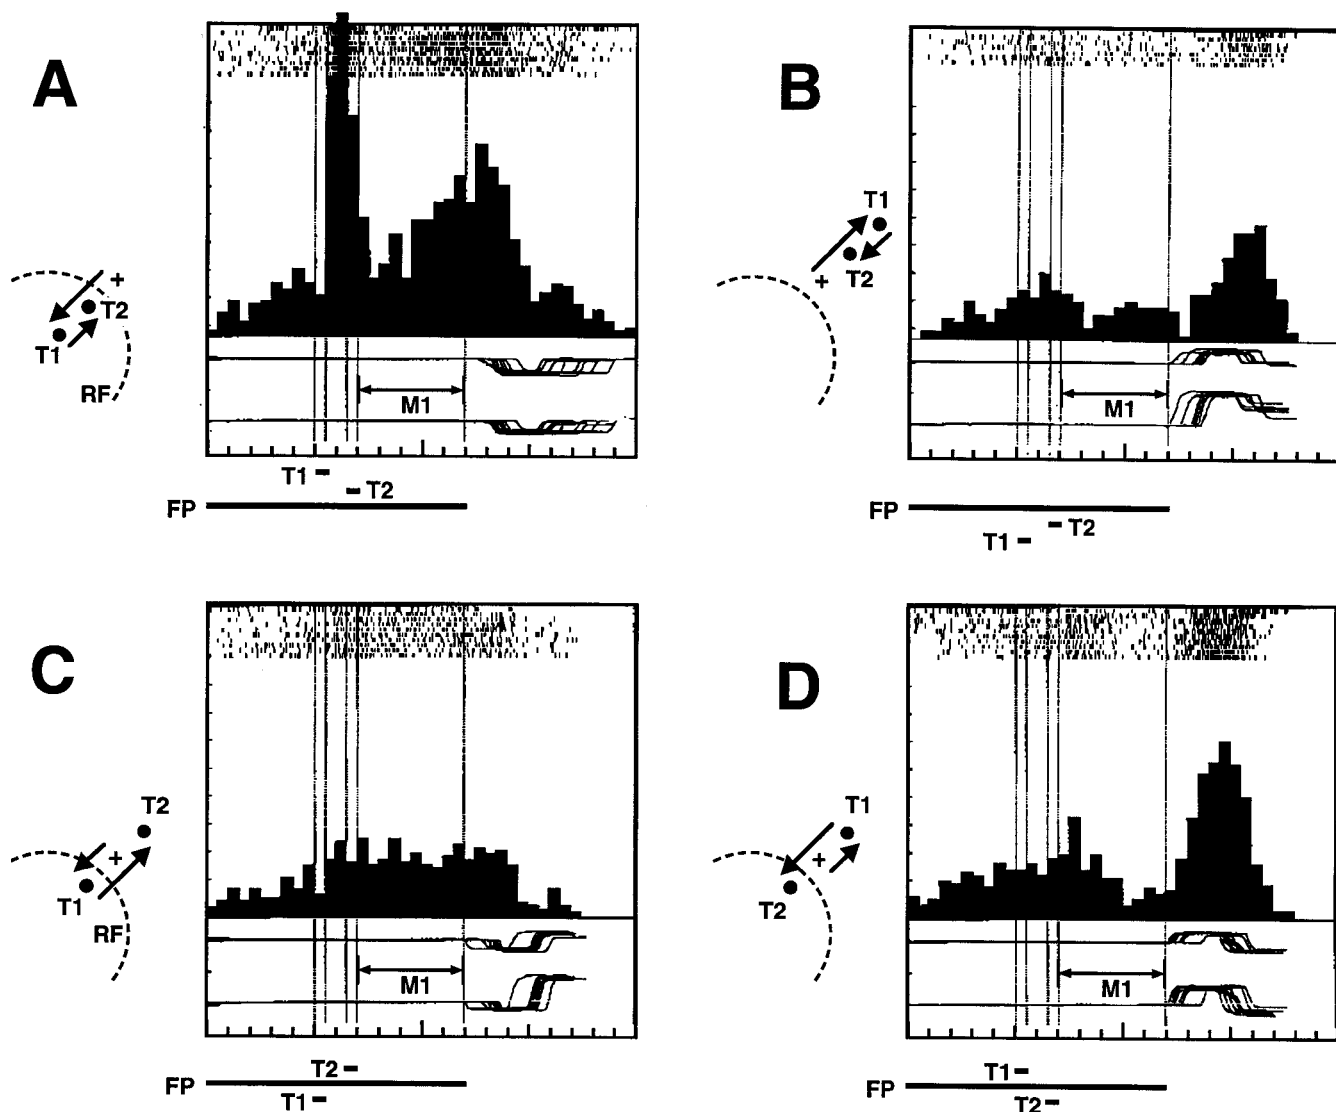

FIGURE 36.7 Activity of a lateral intraparietal (LIP) neuron in four different sequences of a double-saccade paradigm. Each panel has a plot that includes, from top to bottom, the spike rasters for each trial, the time histogram (binwidth, 50 ms) of the firing rate (20 Hz/division in A–C, 25 Hz/division in D), and the horizontal and vertical eye positions (25 degrees/division; abscissa: 100 ms/division). Vertical dotted lines and the

thick horizontal lines below each panel again show the onset and offset of the visual stimuli. Diagrams to the left of each panel show the spatial arrangement of the first and second target (T1 and T2, respectively), the first and second saccades (arrows), and the neuron's receptive field (RF). (Reprinted from Mazzoni and associates, 1996b.)

PRR activity could be referenced to the eye, similar to activity in area LIP. We differentiated between these two possibilities by having monkeys make the same reach, but with the eyes gazing in different directions, or alternatively having them reach to the same location with respect to the eyes, but with the limbs starting from different initial positions. If the neurons were coding in eye coordinates, we would expect different activities for the former condition because identical reaches are made to different retinal locations. However, if the cells are coding in limb coordinates, then activity should vary in the latter condition because limb movements in

different directions are made to the same location with respect to the retina. We found that most PRR cells code reaches in eye coordinates (Batista et al., 1998). The eye-centered responses often were modulated by eye position (Batista et al., 1998). Thus, PRR appears to have the same distributed representation of space as LIP, with their neurons having eye-centered receptive fields modulated by gain fields for eye and other body part positions (figure 36.8).

Establishing a common coordinate frame for both LIP and PRR led us to a rather nonintuitive prediction—that reaches to the remembered locations of sounds in the

PRR and LIP Share a Common Coordinate Frame

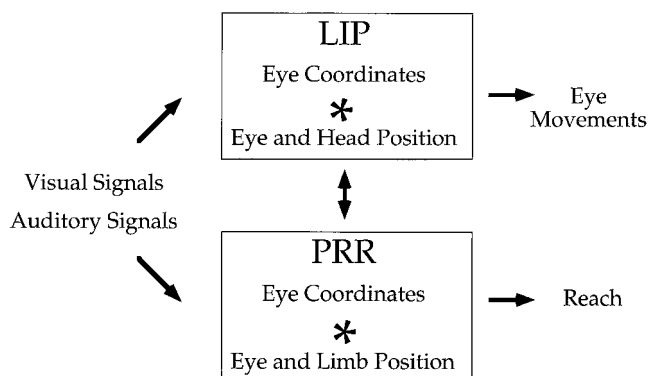

FIGURE 36.8 Both visually and auditorily cued locations are represented in eye coordinates in the lateral intraparietal (LIP) area and the parietal reach region (PRR). Also, both areas have gain modulation of the eye-centered receptive fields by eye and body part positions.

A Distributed Code for the Representation of Space

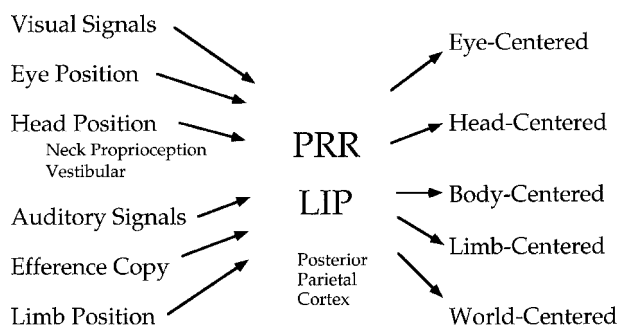

FIGURE 36.9 The eye-centered visual and auditory receptive fields of the parietal reach region (PRR) and the lateral intraparietal (LIP) area are modulated by signals specifying eye, head, and limb position. These modulations produce a common, distributed representation in both areas that can be read out by other parts of the brain in a variety of coordinate frames (including eye, head, body, and even world centered), depending on how the population of neurons in area LIP and PRR are sampled.

dark should be coded in eye-centered coordinates. Of course, in principle, there is no need for this sort of representation. Head-centered auditory signals could be converted directly to limb coordinates for making reaches; there is no need to have an intermediate step of converting these reach signals to eye coordinates. However, if there is a common coordinate frame for both PRR and LIP, then the reach activity should code the target location in eye-centered coordinates and be modulated by eye and limb position signals. Furthermore,

the results from the auditory saccade experiments in area LIP, outlined previously, also predict that the auditory signals would be transformed into eye-centered receptive fields in PRR. This prediction has been substantiated in recent experiments from our laboratory (Cohen and Andersen, 1998). We find that reaches to auditory targets often are coded in eye coordinates in PRR, and these eye-centered receptive fields are strongly gain-modulated by both eye and limb positions. Thus, auditory and visual signals are represented in a similar distributed manner in both LIP and PRR, with eye-centered receptive fields modulated by eye and body position signals (figure 36.8). The advantage of a shared reference frame may be to coordinate communication between the two areas, for instance, during tasks that require the close coordination of the eyes and hands.

Updating lateral intraparietal and parietal reach region spatial representations across saccades

To make an eye movement to a remembered location after intervening saccades requires a mechanism for updating the location of the target. Sparks and Mays (1980) first addressed this intriguing problem in physiologic experiments in the superior colliculus. They found that cells in the intermediate layers updated the location of the next planned eye movement in eye-centered coordinates across saccades. We later showed a similar updating in LIP (Gnadt and Andersen, 1988). Duhamel and

The Remembered Locations Are Maintained in Eye Coordinates Across Saccades in Both PPR and LIP

FIGURE 36.10 Remembered locations are updated in eye coordinates in both the lateral intraparietal (LIP) area and the parietal reach region (PRR). This updating is required not only to ensure that eye-centered locations remain invariant across eye movements, but also for other coordinate frames as well. For instance, when the eye position changes, the eye-gain fields change, and if the eye-centered locations of remembered stimuli are not updated, the correct head-centered location cannot be read out from the population of LIP or PRR neurons.

associates (1992) extended these results to show that a second eye movement was not necessary for this updating to take place. Although they interpreted this updated activity to be sensory, the results of Snyder, Batista, and Andersen (1997, 1998) suggest that this activity may in fact represent default plans for eye movements to the flashed second targets.

We recently asked whether this same updating process takes place in PRR. We presented a visual target for a reach that a monkey was required to remember. However, during the memory period, we then had the monkey make a saccade to fixate a new location in space. Routinely, the remembered location of the reach target was updated in eye coordinates to take into account the change in eye position (Batista et al., 1998). For example, if the monkey made a saccade that brought the remembered location of the target into the retinal receptive field of the PRR neuron, then it became active during the delay period before the reach. If the saccade brought the remembered location out of the receptive field of PRR cell, then it fell silent. Again, LIP and PRR were found to share an important similarity, both updating remembered locations in eye coordinates across saccades (figure 36.10). We also have seen the same updating in eye coordinates for locations cued by auditory targets (Cohen and Andersen, 1998).

This finding has important consequences for reading out the distributed representation of space accurately in nonretinal coordinates. If the eyes move, the eye position signals and gain modulations in LIP and PRR change in accordance with the new eye position. If the remembered retinal location of a target remains the same after the eye movement it is coded incorrectly in head- or body-centered coordinates. Thus, the updating of location in eye coordinates is necessary to read out the correct location with respect to the head or body.

Conclusions

The results reviewed previously show that areas LIP and PRR share several common features, even though one area is related to planning eye movements and the other is related to activity in reach movements. These common features include the following:

1. Both code visual and auditory targets in eye centered coordinates (figure 36.8);
2. Both demonstrate gain fields for eye and other body part positions (figure 36.9);
3. Activity in both areas code the next planned movement; and
4. Planned movement activity is updated across eye movements (figure 36.10).

These common features, particularly points 1 and 2, indicate that the two areas use a common coordinate frame. This coordinate frame is distributed and can be read out by other areas in several different reference frames. The specificity of their activity for the type of movement, and the fact that the cells only code the next planned movement (point 3), indicates that both areas code intentions to move. Whether these two areas of the PPC establish the basic rules for processing for other areas in the PPC remains to be seen.

37 Neural Mechanisms of Motor Cognitive Processes: Functional MRI and Neurophysiological Studies

APOSTOLOS P. GEORGOPOULOS

ABSTRACT The neural mechanisms of cognitive processes cannot be elucidated using a single method; instead, useful insight can be gained by employing various approaches. In this chapter, the author attempts a discussion in this direction, namely the investigation of the mechanisms underlying some motor cognitive processes using behavioral, neurophysiological, and functional neuroimaging methods.

At the extremes, pure motor or cognitive processes are separate, for example, in the cases of the stretch reflex or mental calculation. However, they commonly are associated to varying degrees, for example, when you play chess. In fact, chess playing can be regarded as a motor-cognitive task par excellence because it consists essentially of actual and imagined movements of the chess pieces and the hand. During the past several years, we have developed two tasks at the interface of motor and cognitive processing and used them to investigate the neural mechanisms underlying their performance. Specifically, both tasks require the making of hand movements at a different direction from a stimulus direction but based on different rules. In both tasks, human subjects and monkeys moved a two-dimensional (2-D) handle and responded to visual stimuli appearing on a display. In the first task, the movement had to be at a constant angle from the stimulus direction (Georgopoulos and Massey, 1987), whereas in the second task, the movement had to be selected based on the serial order of stimuli in a sequence (Georgopoulos and Lurito, 1991). The mechanisms involved in these two tasks were investigated using classical chronometric, experimental psychological methods (Georgopoulos and Massey, 1987; Georgopoulos and Lurito, 1991), functional magnetic resonance imaging (fMRI) of the brains of human subjects (Tagaris et al., 1998), and recording of the activity of single cells in the brain of behaving monkeys

(Georgopoulos et al., 1989; Lurito, Georgakopoulos, and Georgopoulos, 1991; Pellizzer, Sargent, and Georgopoulos, 1995). Each of these investigations provided unique, crucial insights into the processes involved that were complementary with each other. However, each of these sets of studies gives only a partial view of the whole, and it is only after all the results are looked at together that one can get a more adequate glimpse of the whole problem. Following is a summary of the essential findings from these individual studies, with an attempt at the end to sketch the whole as I see it emerge from these partial views.

Behavior

In the mental rotation task, the subject had to move a handle at an angle (clock- or counterclockwise [CCW]) from a stimulus direction. Thus, the direction of the movement was spatially connected to the direction of the stimulus and was at a constant angular relation to it. Experiments in human subjects (Georgopoulos and Massey, 1987) showed that the response time (RT) increased as a linear function of the instructed angle. This finding suggested that the psychological process in this task involves a mental rotation of the motor intention from the direction of the stimulus to the direction of the movement. This is similar to the mental rotation of visual images proposed by Shepard and colleagues (see Shepard and Cooper, 1982) in a different setting.

In the context-recall memory-scanning task, the subject had to move the handle in a direction specified by a serial order rule with respect to the onset of a particular stimulus in a sequence. Two to seven stimuli were presented successively on a circle (list stimuli), and then one of them (except the last one) was shown again (test stimulus); the subject was required to move in the direction of the stimulus that followed the test stimulus in the list sequence. In this case, the RT was a linear function of the number of list stimuli (Georgopoulos and Lurito,

APOSTOLOS P. GEORGOPOULOS Brain Sciences Center, Veterans Affairs Medical Center and Cognitive Sciences Center, Departments of Neuroscience, Physiology, Neurology, and Psychiatry, University of Minnesota, Minneapolis, Minn.

1991). This finding suggested a memory scanning operation analogous to the one suggested by Sternberg (1969) for a visual recognition task.

Thus, these two tasks required that movements be made away from a stimulus direction but based on different rules, namely a spatial transformation or a temporal order rule. The monotonic increase of the RT with key task variables suggested two different psychological processes as the cardinal features of these tasks, namely mental rotation in the former and memory scanning in the latter task. The next step was to find out which brain areas are involved in these processes and how information is being processed at the neuronal level. For the former objective, we used fMRI; for the latter, we employed single-cell recordings in behaving monkeys.

Functional magnetic resonance imaging of mental rotation and memory scanning

GENERAL CONSIDERATIONS Functional brain imaging provides a means by which the patterns of activation of various brain areas in a task can be determined. The main advantage of these techniques is that they can provide functional activation images of the whole brain, but they lack functional specificity at the cellular level because the “activation” reflects changes in blood flow or metabolic signals that only indirectly relate to neuronal activity. Therefore, the data obtained from such studies are interpretable only in the context of other information (e.g., from neuropsychological or neurophysiological studies) concerning the role of specific areas in particular tasks. These considerations are exemplified in the results of our studies, discussed in a subsequent section.

THE TASKS USED: COGNITIVE OPERATIONS AND THEIR OPERANDA Cognitive processes do not happen in vacuo; essentially, they are operations carried out on operanda. For example, mental arithmetic operates on mental representations of numbers. A major objective of our studies has been to design experimental paradigms in which cognitive operations of interest and their operanda are chosen so as to provide distinct task dimensions. These task dimensions provide, in turn, an abstract space that serves as a guidepost for interpreting the results of functional imaging studies, an explanation of which follows.

We used four cognitive tasks in these experiments (Tagaris et al., 1998). They were combinations of two cognitive processes (mental rotation and memory scanning) operating on two kinds of operanda (visual images and intended arm movement direction). Thus, four operation–operandum combinations were generated, as il-

lustrated in figure 37.1. We wanted to identify the brain activation patterns for each one of the four tasks and, hopefully, relate them in some abstract way to the tasks themselves. The crucial question is: Can we recover the dimensions of the tasks (i.e., operation and operandum) from the brain activation patterns?

Typical trials of the four cognitive tasks used are illustrated in the first column of figure 37.2 (see also color plate 22), and trials of matched “control” tasks are illustrated in the second column. In the visual mental rotation task (figure 37.2A), the letter G was shown rotated from -160° to $+160^{\circ}$ from the upright at 20° intervals, in a random order in different trials. Normal and mirror images of the letter were presented for each angle above. Subjects responded by pressing the left or the right of two buttons to indicate whether the letter was in normal or mirror image orientation, respectively. In the control task (figure 37.2), the same letter was shown in normal and upright positions, and the subjects responded simply by pressing a button without having to make any judgment. In the movement mental rotation task (figure 37.2B), an instruction angle was shown for 900 ms and was followed by a stimulus in 1 of 12 positions on a circle, every 30° ; 12 stimuli were shown for each of five instruction angles (30° to 150° CCW, every 30°) in a randomized block design. Subjects responded by moving a joystick-controlled cursor in a direction away from the stimulus at the instructed angle. In the control task, a zero angle was instructed, and subjects responded by moving the joystick in the direction of the stimulus shown. In the context-recognition visual memory-scanning task (figure 37.2C), a sequence (list) of two to seven visual stimuli was shown in a random order on a circle, and then two consecutive (test) stimuli were shown again in the same or reverse sequence; subjects responded by pressing the left or the right of two buttons to indicate whether the two test stimuli were presented

FIGURE 37.1 Experimental task design.

in the original or reverse sequence, respectively. In the control task, two to seven stimuli were shown but only one as a test stimulus, and the subjects responded by pressing a button without having to make any judgment. Finally, in the context-recall movement memory-scanning task (figure 37.2D), a sequence of two to seven stimuli was shown in a random order on a circle, and then one (test) stimulus (except the last) was shown again; subjects responded by moving a joystick-controlled cursor in the direction of the stimulus that was presented next to the test stimulus in the sequence. In the control task, the same display was shown, and the subjects responded by moving the joystick in the direction of the test stimulus. For both memory-scanning tasks, eight circular positions were used, every 45°. Each visual stimulus was shown for 600 ms and then went off while the next stimulus came on; the delay from the end of the presentation of the last stimulus to the onset of the first test stimulus was 900 ms.

Each of these four cognitive tasks was performed during the “task period,” which was preceded and followed by a “control period,” during which the corresponding control tasks were performed. The sequence of presentation of these four tasks was randomized. Key presses and directed movements were recorded using a nonmagnetic keypad and joystick, respectively. Directed movements were considered correct when they were within +30° from the required direction. The response time was measured with a precision of 1 ms. Eye movements were recorded during performance in the magnet by electro-oculography using Ag/AgCl electrodes and graphite wires. In general, eye movements were infrequent during data acquisition.

THE ISSUE OF CONTROL TASKS As expected, the RT increased as a linear function of the angle of rotation in the two mental rotation tasks or of the number of list stimuli in the two memory-scanning tasks used (data not shown). This suggests that the hypothesized operations were indeed employed in these tasks. The crucial item in interpreting the following results concerns the tasks performed during the control period because the judgment on whether a brain area was involved or not in these tasks rested on a statistical comparison between the fMRI signal during the task period and that during the control period. As explained previously, the control tasks differed for each of the four cases because our objective was to factor out the visuomotor events between the control and task periods, and thus isolate the particular cognitive condition under study, that is, the particular combination of a cognitive operation (i.e., mental rotation or memory scanning) and its operandum (i.e., visual image or intended arm movement direction) (figure 37.1).

This design is crucial because if the control tasks were not matched for the corresponding cognitive ones with respect to simple visuomotor events (e.g., if, during the control period, the subjects simply rested with eyes closed), then the comparison between task and control periods would have reflected differences in simple sensorimotor processing in addition to the aforementioned cognitive aspects. Therefore, for the interpretation of the following results, the brain activation patterns observed refer to the cognitive aspects of the tasks employed.

BRAIN ACTIVATION PATTERNS Functional activation maps were derived from fMRI images acquired at high magnetic field (4 Tesla; see Tagaris et al., 1998, for the technical details of data acquisition and initial statistical processing). Overall, a conservative combination of criteria was used to identify highly consistent activation. The assignment of activated pixels to specific areas was based on anatomic landmarks in 2-D images and in three-dimensional (3-D) reconstructions of brain volumes (VoxelView/Ultra 2.5, Vital Images Inc., Fairfield, IA) as well as on Talairach coordinates (Talairach and Tournoux, 1988). Thirty brain areas were used for these analyses. The percentages of subjects ($N = 10$ subjects, 5 women and 5 men) in whom a specific area was activated in a given task are shown as shades of gray in figure 37.3; the columns represent brain areas, and the rows represent the four cognitive tasks used. Thus, a whole column shows the varying consistency of involvement of a given area in the four tasks, whereas a whole row shows the varying involvement of the various areas in a given task. This representation can be interpreted as a probability map that depicts the probability that a particular area will be activated during performance of a given task; alternatively, this representation can be interpreted as a consistency map, which shows the consistency by which a particular brain area will be activated in a given task. This is a quantitative way of analyzing binary functional activation maps, that is, brain maps in which an area of interest is considered either activated or not. Usually, such maps are treated descriptively, and little if any use is made of the information pertaining to the consistency of activation of a given area across subjects. In contrast, we used precisely this information in our analyses because it is the primary datum at the level of the population of subjects imaged.

MULTIDIMENSIONAL SCALING: GENERAL CONSIDERATIONS Multidimensional scaling (MDS) is a multivariate analysis technique by which a representation in a high-dimensional space is reduced to a representation in a low-dimensional space while trying to keep the relative

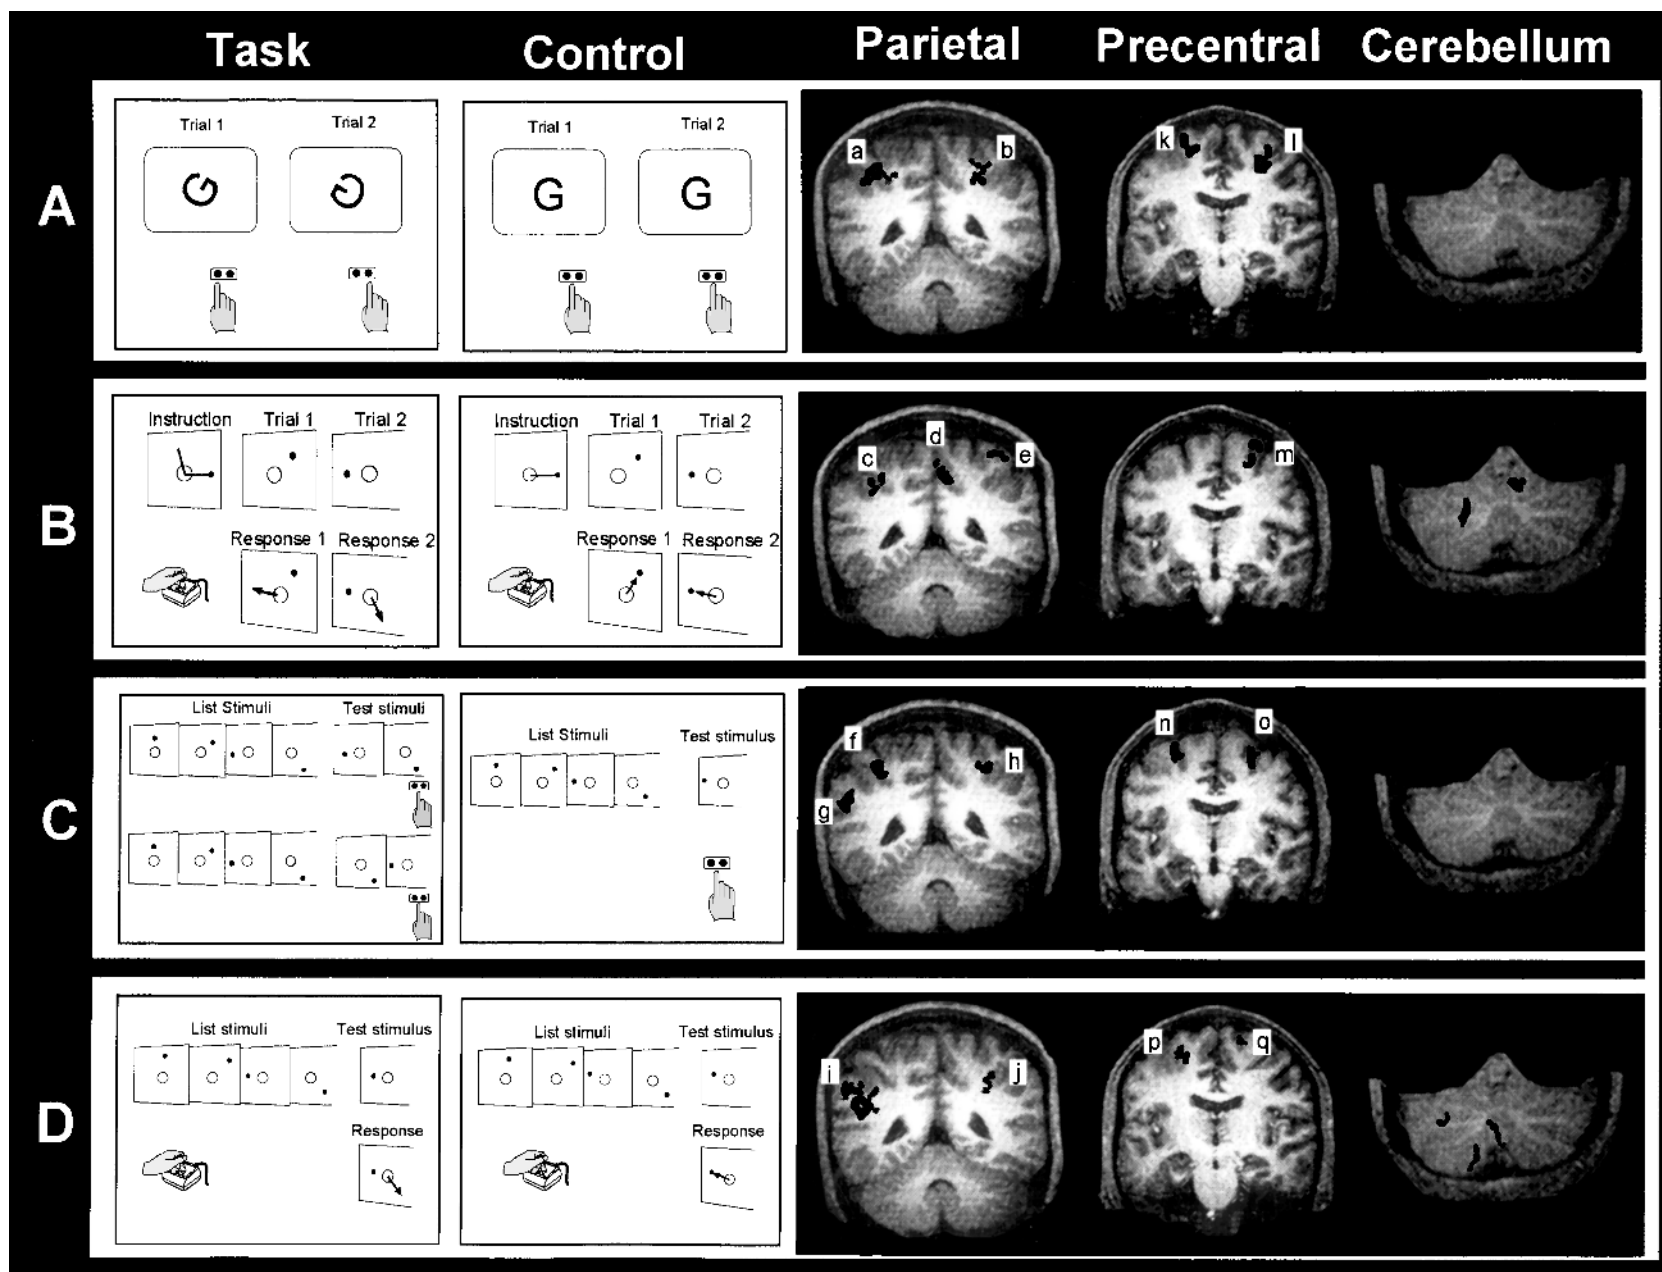

FIGURE 37.2 Schematic drawings of the tasks used and functional activation maps from one subject. (A) Visual mental rotation; (B) motor mental rotation; (C) visual memory scanning; (D) motor memory scanning. *Task*: experimental tasks. *Control*: control tasks. The control tasks were designed so that the visual display and the motor responses were very similar with those of the corresponding experimental tasks. Therefore, the functional activation maps reflect the combination of task dimensions and not sensorimotor events. *Activation*: Functional activation maps illustrate typical examples from one subject. Areas a, b, c, f, h, and j correspond to the intraparietal sulcus. Area e corresponds to the right superior parietal lobule. Areas g and h correspond to the left inferior parietal lobule. Areas k through q correspond to the precentral gyrus. Talairach coordinates for the center of activation shown (in mm on mediolateral, anterior-posterior, and inferior-superior axis) are as follows: a:33/-40/ 44; b: 30/-38/ 46; c: 32/-40/ 43; d: 1/-35/-45; e: 32/-39/ 52; f: 32/-40/ 45; g: 46/-43/ 28; h: 31/-39/45; i: 45/-43/ 30; j: 34/-38/ 36; k: 17/-19/ 59; l: 25/-20/-55; m: 23/-16/ 64; n: 22/-15/ 61; o: 24/-16/ 58; p: 18/-20/ 60; q: 12/-21/67.

distances between corresponding points in the two spaces as similar as possible (Shepard, 1980). The data entered in this analysis consist of dissimilarities (e.g., Euclidean distances) between pairs of measurements, commonly arranged in a symmetric “dissimilarity” matrix. The main outcome of MDS is a plot of the variable of interest (e.g., stimuli or tasks) in what is called derived configuration space. The dimensions of this space are usually two, as one strives to reduce the number of original dimensions as much as possible, but the choice of the number of the reduced dimensions is somewhat arbitrary. Therefore, it is especially useful if this choice is guided by considerations other than those of parsimony.

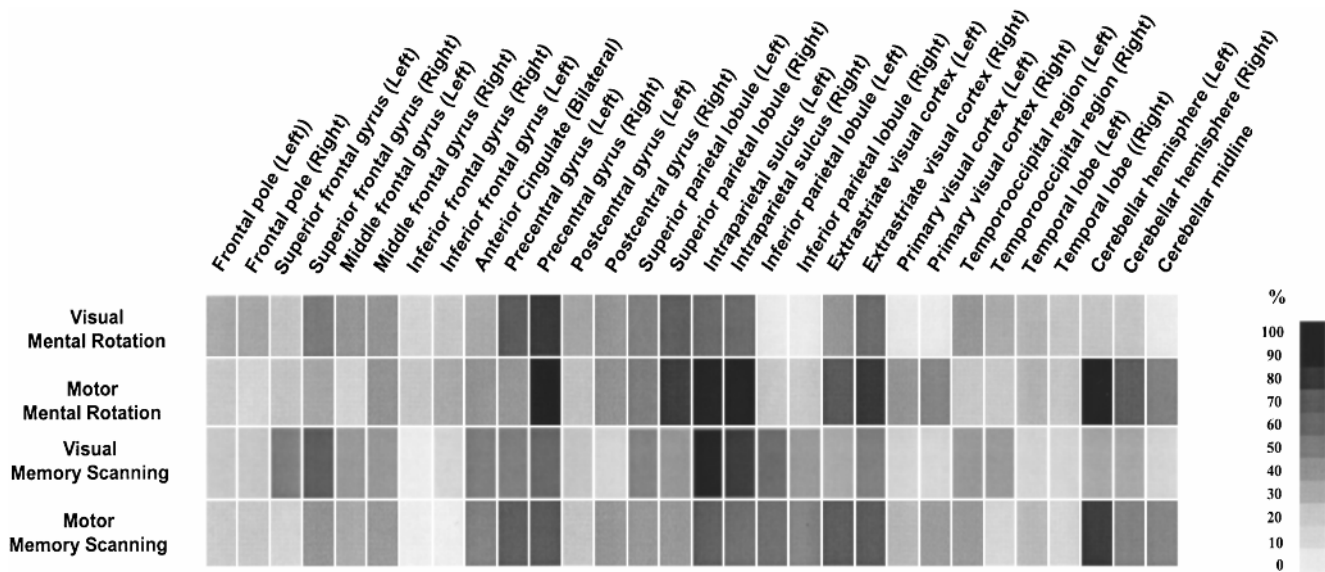

FIGURE 37.3 Schematic diagram showing the percentage of subjects who showed activation of the areas indicated ($N = 10$

Such considerations existed in the present application, for which the configuration space was that of the four cognitive tasks; because, by design, we had two dimensions in the task domain (one for the cognitive operation and another for the operands, see figure 37.1), a choice of two dimensions was dictated for the configuration space. This also provided a substantial reduction in dimensionality of the original space, from a 30-dimensional brain area space to the 2-D task configuration MDS space.

The MDS analysis can be performed on a single dissimilarity matrix. However, if several such matrices are available for a given problem, each individual matrix can be weighted separately in the analysis, resulting in what is called weighted MDS (WMDS), or individual scaling (INDSCAL) procedure, which we used. In the present application, we had data concerning the functional activation of each one of 30 brain areas for the four tasks used; therefore, we constructed $30 \times 4 \times 4$ dissimilarity matrices and used the INDSCAL procedure of the SPSS statistical package (version 7, SPSS, Inc., Chicago, IL, 1996) for a weighted MDS. There are two additional advantages of the WMDS. One is that the position of the points in the derived configuration space is fixed, which makes the dimensions potentially interpretable. And the other is that it yields an additional plot showing what is called derived subject weights. In this plot, the points plotted correspond to the individual “subjects” (in the present case, these are the brain areas), and the axes are exactly the same as those in the task configuration space. Although it looks like a scatter plot, this is a vector plot: all vectors originate from the origin of the axes and end on the plotted points; therefore,

subjects). (Reprinted from Tagaris et al., 1998, Copyright 1998, page 110, with permission from Elsevier Science.)

there are as many vectors as points plotted. For the interpretation of this plot, the task configuration space plot is derived by weighting individual dissimilarity matrices, and, therefore, it represents an overall “average” configuration, which may or may not be optimal for a particular “subject.” The vectors in the derived subject weight plot concern these aspects, which are reflected in the length of the vector and its angular orientation. Specifically, in our application, the length of a vector (from 0 to 1) indicates how “good” the derived task configuration space is for a particular brain area: the longer the vector, the closer this configuration “suits” this brain area. Conversely, the orientation of the vector indicates the relative importance of the two dimensions for this area, as reflected in the ratio of the projections of the vector on the two axes (i.e., the slope of the line). This means that if the dimensions are interpretable, then a statement can be made about the relative participation of a brain area in the aspect(s) reflected in these dimensions.

MULTIDIMENSIONAL SCALING: RESULTS The task configuration space derived using INDSCAL and a ratio level of measurement is shown in figure 37.4. Twenty-nine areas contributed to this analysis. (One area was dropped because it yielded a dissimilarity matrix of all zeros. This area was the right middle frontal gyrus, which was activated in exactly the same number of subjects in all four tasks [figure 37.3] and, therefore, could not provide information differentiating these tasks.) It can be seen that the four points corresponding to the

four cognitive tasks used fell in each of the four quadrants such that the two dimensions could be identified as relating to the operation (ordinate) or the operandum (abscissa). In fact, these were the two task dimensions by design, as illustrated in figure 37.1. These results mean that the MDS analysis recaptured the cognitive-psychological dimensions of the tasks from the brain activation patterns. Figure 37.5 recapitulates this correspondence by showing the formal similarity between the planned task dimensions (left panel) and the derived task dimensions (right panel). This is a remarkable finding and a tribute to the power of MDS as a tool by which to analyze complex neuroimaging patterns of activation.

Figure 37.6 plots the derived area weights. It seems that the vectors plotted fall into three groups, as follows. The first group is closer to the abscissa, the second is around the main diagonal, and the third is closer to the ordinate. Our interpretation of this plot is along the lines discussed previously; namely, that the areas in the first group are involved with the dimension of the abscissa (i.e., operandum), those of the third group with the dimension of the ordinate (i.e., operation), whereas those in the middle are involved with both dimensions. The second point concerns the goodness of fit of the derived task configuration space for particular brain areas. As aforementioned, this is indicated by the length of the vector: the longer the vector, the better the goodness of fit. (Other measures also can be used, such as Kruskal’s stress formulae or R^2 .) Interestingly, in figure 37.6, the vectors closest to the axes were longer than those in the middle, with lengths close to the maximum possible value of one. This suggests that in the context of the tasks used, brain areas are rather specialized in processing information concerning the cognitive operation or its operandum, rather than dealing with both of them. Finally, this plot provides interesting information regarding the possible involvement of particular areas in these functions. Thus, the areas with a good fit (e.g., long vectors) that presumably are concerned with the operandum dimension (group nearest to the abscissa) included occipital (primary visual and extrastriate cortex bilaterally), cerebellar areas (cerebellar hemispheres bilaterally and cerebellar midline), and the left middle frontal gyrus. The areas presumably concerned with the operation dimension (group nearest the ordinate) included parietal areas (inferior parietal lobule bilaterally, right superior parietal lobule), the right temporal cortex, and the anterior cingulate gyrus (this area was not split in left and right). All other areas had shorter vectors or belonged to the group in the middle.

Thus, the MDS analysis provided a novel way by which neurobehavioral relations were explored. It re-

Multidimensional Scaling (INDSCAL):

Derived Task Configuration

FIGURE 37.4 Task configuration space derived by multidimensional scaling (MDS), individual scaling (INDSCAL) model (see text for details).

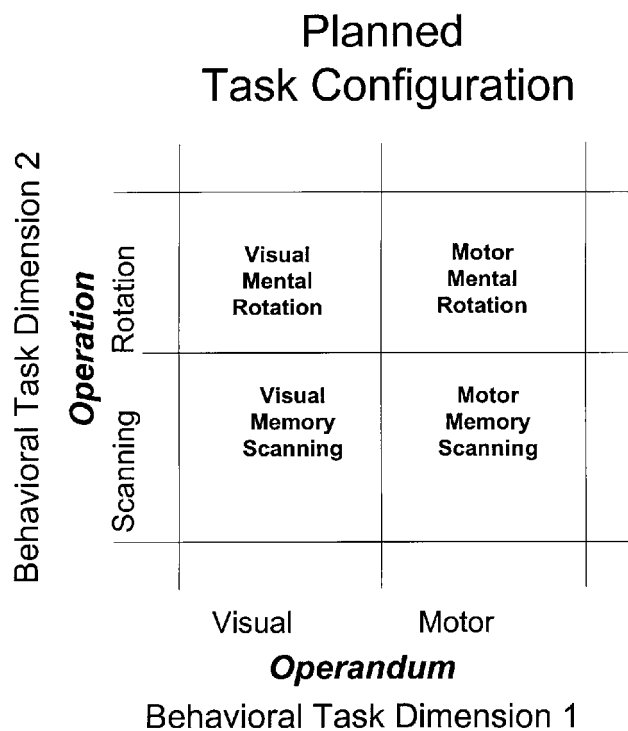

FIGURE 37.5 Interpretation of the results of the multidimensional scaling analysis illustrated in figure 37.4. Left: Experimental task design, as depicted in figure 37.1. Right: Same plot

as that of figure 37.4, but here the axes are interpreted to indicate the task dimensions, as on the left panel.

covered the task dimensions from the brain activation patterns and identified areas specifically associated with those dimensions. By necessity, the grain of exploring brain function based on any kind of analysis is constrained by the grain of separating brain areas. In the present analyses, this grain was more coarse for some areas (e.g., extrastriate cortex and cerebellum) than for others (such as the parietal areas). A finer parcellation of anatomic areas can be achieved by several means, such as using finer anatomic landmarks or additional tasks known to activate certain areas. In any case, this is an open-ended problem, and, most probably, it always will be desirable to strive for even finer parcellations. However, as more and more areas are distinguished, correlations in their patterns of activation also are likely to increase, which essentially will limit the usefulness of this approach. Of course, a crucial objective is to determine the level of the coarseness of the grain necessary and sufficient for a given study, and it is likely for this to differ from study to study. Therefore, this remains an active field of investigation. However, the present study captured a bird's eye view of the specific problem, and, given the encouraging results obtained, it seems that the parcellation of brain areas used might have not been very far from the appropriate one for this study.

Single cell neurophysiology of mental rotation and memory scanning

GENERAL CONSIDERATIONS As aforementioned, the signal measured by functional neuroimaging methods is related only indirectly to the electrophysiological activity. Crucial validation studies have shown a correspondence between the expected activation of a brain area (e.g., visual cortex, motor cortex) based on prior neurophysiological evidence and the one actually observed using neuroimaging (e.g., see Ogawa et al., 1992; Kim et al., 1993). However, the situation becomes fairly complicated when more complex tasks are considered because a change in a neuroimaging signal (e.g., blood flow in PET or BOLD activation in fMRI) is not uniquely associated with neurophysiological events, such as excitation or inhibition. The detailed cellular mechanisms can be investigated only by using suitable methods, and one of the finest ones is the recording of single cell activity in behaving animals. The impulse activity is recorded by microelectrodes, and several such electrodes can be employed to record simultaneously the activity of many cells (Eichenbaum and Davis, 1998). The spike trains thus collected then are analyzed with respect to behavioral events, and the relations between these two kinds of data are analyzed. Therefore, the major advantage of this

FIGURE 376 Brain area weight plot derived by individual scaling (INDSCAL) model. The numbers in the plot correspond to the following areas: 1, left primary visual cortex; 2, right primary visual cortex; 3, left extrastriate visual cortex; 4, right extrastriate visual cortex; 5, left superior parietal lobule; 6, right superior parietal lobule; 7, left intraparietal sulcus; 8, right intraparietal sulcus; 9, left inferior parietal lobule; 10, right inferior parietal lobule; 11, left cerebellar hemisphere; 12,

right cerebellar hemisphere; 13, cerebellar midline; 14, left temporooccipital region; 15, right temporooccipital region; 16, left temporal lobe; 17, right temporal lobe; 18, left postcentral gyrus; 19, right postcentral gyrus; 20, left precentral gyrus; 21, right precentral gyrus; 22, left superior frontal gyrus; 23, right superior frontal gyrus; 24, left middle frontal gyrus; 25, left inferior frontal gyrus; 26, right inferior frontal gyrus; 27, bilateral anterior cingulate; 28, left frontal pole; 29, right frontal pole.

method is its fine grain and the detail by which it can probe cellular mechanism, but its drawback is that it can only explore a very limited part of the brain (usually of the order of millimeters), especially as compared with neuroimaging methods that can scan the whole brain in a matter of seconds. It is obvious that each of the two methods can provide important, albeit partial, information about the brain mechanisms of behavior. In our studies, we have been using both of these methods to obtain this kind of complementary information. The results of our analyses of fMRI data during mental rotation and memory scanning were described in the preceding section; in what follows, we discuss the results of neurophysiological studies in monkeys trained to perform the aforementioned movement mental rotation and movement memory-scanning tasks. However, we summarize first the neural coding of movement direction by motor cortical cells.

NEURAL CODING OF MOVEMENT DIRECTION The activity of single cells in the motor cortex is tuned directionally—that is, cell activity is highest for a given direction (“preferred direction”) of movement and decreases gradually with directions farther and farther away from the preferred one (Georgopoulos et al., 1982; Amirikian and Georgopoulos, 1998). Typically, the frequency of cell discharge varies as a linear function of the direction cosines of the movement vector (relative to its origin), or, equivalently, of the cosine of the angle formed between the direction of a particular movement and the cell's preferred direction (i.e., the direction of movement for which cell activity would be highest). Preferred directions differ for different cells and are distributed uniformly in 3-D space (Schwartz, Kettner, and Georgopoulos, 1988). Finally, the preferred direction is very similar for movements of different amplitudes (Fu, Suarez, and Ebner, 1993).

Single cells provide only the building elements of the neural construct underlying movement generation and control: this construct invariably involves populations of neurons. The use of neuronal populations in this context differs from common statistical measures of populations, such as averages, variances, and frequency distributions of functional cell properties. Instead, the hypothesis is that a single neuron carries only partial information about a movement parameter that therefore is represented uniquely in the whole neuronal ensemble. This analysis was applied to the coding of the direction of movement, as follows. The broad directional tuning indicates that a given cell participates in movements of many directions; from this result, and from the fact that preferred directions range widely, it follows that a movement in a particular direction engages a whole population of cells. A unique code for the direction of movement was proposed (Georgopoulos et al., 1983; Georgopoulos, Schwartz, and Kettner, 1986; Georgopoulos, Kettner, and Schwartz, 1988) that regarded this population as an ensemble of vectors. Each vector represents the contribution of a directionally tuned cell; it points in the cell's preferred direction and is weighted (i.e., has length) according to the change in cell activity associated with a particular movement direction. The weighted vector sum of these neuronal contributions was called the "neuronal population vector." The population vector points in the direction of reaching (Georgopoulos et al., 1983; Georgopoulos, Schwartz, and Kettner, 1986; Georgopoulos, Kettner, and Schwartz, 1988; Kalaska, Caminiti, and Georgopoulos, 1983; Kalaska et al., 1989; Fortier, Kalaska, and Smith, 1989; Caminiti et al., 1991). Although preferred directions tend to change in the horizontal plane as the origin of the movement changes, the population vector remains an unbiased predictor of the direction of the movement (Caminiti et al., 1991). Three aspects of the population vector analysis are remarkable: its simplicity, its robustness, and its spatial outcome. With respect to simplicity, the ongoing calculation of the population vector is a simple procedure, for it (1) assumes the directional selectivity of single cells, which is apparent, (2) involves weighting of vectorial contributions by single cells on the basis of the change in cell activity, which is reasonable, and (3) relies on the vectorial summation of these contributions, which is practically the simplest procedure to obtain a unique outcome. With respect to robustness, the population vector is a robust measure, for it still can convey a good directional signal even with only 100 cells (Georgopoulos, Kettner, and Schwartz, 1988). Finally, the population vector is a directional measure, isomorphic direction in space. Indeed, the population analysis transforms aggregates of

purely temporal spike trains into a spatiotemporal signal.

These properties of the population vector suggest that it may be robust in the temporal domain as well. Indeed, when it was calculated as a time-varying signal every 20 ms, it provided an accurate prediction during the response time regarding the upcoming movement trajectory (Georgopoulos et al., 1984; Georgopoulos, Kettner, and Schwartz, 1988). This finding demonstrated the feasibility of using the population vector as a measure of the directional tendency of a neuronal ensemble and gave the impetus to new studies in which delays were imposed such that the movement was initiated after a period of time following a cue stimulus and in response to a "go" signal. The first of these studies (Georgopoulos, Crutcher, and Schwartz, 1989) involved an instructed delay period: The cue stimulus came on and stayed on while the monkey waited immobile for the occurrence of the go stimulus, which triggered the movement. Under those conditions, the population vector pointed during the delay in the direction of the cue, which was the same as that of the upcoming movement. Therefore, using this analysis, the directional information in the neuronal ensemble could be identified during the waiting period. The second study (Smyrnis et al., 1992) went a step further and included a memorized delay period: The cue stimulus came on but stayed on for only 300 ms, after which it was turned off. There ensued a memorized delay period during which the monkey waited immobile for the occurrence of the go signal but during which there was no target stimulus on display. The monkey was required to move, at the presentation of the go signal, in the direction of the (now absent) cue. Therefore, this cue direction had to be kept in memory during the delay period. Indeed, the population vector pointed in the direction of the memorized cue direction during the delay period. The results of these delay studies demonstrated the usefulness and power of the population vector analysis by which to monitor in time cognitive operations. In the two subsequent experiments discussed next, the tasks used required transformations of the intended direction of movement, one based on a spatial rule (mental rotation task) and another based on a temporal order rule (context-recall memory scanning task). These two tasks were very similar to the movement mental rotation and memory-scanning tasks used in the fMRI studies, as discussed previously. Therefore, they provide two interesting cases in which to compare the results and their implications for the neural mechanisms involved.

Neurophysiology of motor mental rotation The knowledge gained from single-cell and population analyses

with respect to the neural coding of the direction of movement was applied to interpret changes in neuronal activity when a transformation was imposed on the upcoming movement, namely that it points in a direction at an angle from a reference direction indicated by a stimulus on the plane. In these experiments (Georgopoulos et al., 1989; Lurito, Georgakopoulos, and Georgopoulos, 1991), rhesus monkeys were trained to move a handle 90° CCW from a reference direction (“transformation” task); these trials were intermixed with others in which the animals moved in the direction of the target (“direct” task). The cell activity in the arm area of the motor cortex (contralateral to the performing arm) were recorded extracellularly. The neural activity was analyzed at the single-cell and neuronal population levels. We found the following. The changes in the activity of single cells in the direct task were related to the direction of movement, as described previously (Georgopoulos et al., 1982). The cell activity also changed in the transformation task, but there were no cells that changed activity exclusively in this task. Therefore, at the level of the motor cortex, the required transformation did not seem to involve a separate neuronal ensemble. The patterns of single-cell activity in the transformation task frequently differed from those observed in the direct task when the stimulus or the movement was the same. More specifically, cells could not be classified consistently as “movement”- or “stimulus”-related because frequently the activity of a particular cell would seem “movement-related” for a particular stimulus-movement combination, “stimulus-related” for another combination, or unrelated to either movement or stimulus for still another combination. Thus, no obvious insight could be gained from such an analysis of single-cell activity. However, an analysis of the activity of the neuronal population using the time evolution of the neuronal population vector revealed an orderly rotation of the neuronal population vector from the direction of the stimulus toward the direction of the movement through the 90° CCW angle (figure 37.7) (Georgopoulos et al., 1989; Lurito, Georgakopoulos, and Georgopoulos, 1991). There are several points of interest in this analysis that were surprising. First, there was no a priori reason to expect that the population vector would point to any other direction than the direction of the movement, on the simple hypothesis that the motor cortex is involved only in the production of movement. Our interpretation of the population vector as the directional motor intention suggests that in the transformation task, the motor intention is not restricted to the movement direction but occupies intermediate directions during the reaction time. Second, there was no a priori reason to expect that the popula-

tion vector would shift in an orderly fashion in the CCW direction, for no explicit instruction was given to the animals to that effect. The results obtained suggest that the directional motor intention spanned the smallest angle. This could, presumably, minimize the time and computational load involved in the transformation required.

The hypothesis was tested that this apparent rotation of the population vector could be the result of activation of two subsets of cells, one with preferred directions at or near the stimulus direction and another with preferred directions around the direction of movement: if cells of the former type were recruited at the beginning of the reaction time, followed by those of the second type, then the vector sum of the two could provide the rotating population vector. However, such a preferential activation of “stimulus direction”-centered and “movement direction”-centered cells was not observed. Conversely, a true rotation of the population vector could be reflected in the engagement of cells with intermediate preferred directions during the middle of the reaction time. Indeed, such a transient increase in the recruitment of cells with intermediate (i.e., between the stimulus and movement) preferred directions during the middle of the reaction time was observed. This supports the idea of a true rotation of the population signal. Finally, a rotation of the population vector through several angles, including 180°, has been described in a different context (Wise, di Pellegrino, and Boussaoud, 1996).

Neurophysiology of motor memory scanning This task required that a movement be made in a direction away from a stimulus direction based on a temporal, serial order rule (Pellizzer, Sargent, and Georgopoulos, 1995). This is a very different rule from the spatial one applied to the task described in the preceding section. Two monkeys were trained to perform a task that was very similar to the movement memory-scanning task described in the fMRI section. Briefly, two to five list stimuli were presented on a circle every 0.65 s at pseudorandom locations; when one of them (except the last) changed color (test stimulus), the monkeys made a motor response toward the next light in the sequence. Obviously, unlike the mental rotation task, in this task, the direction of the motor response bears no consistent relation to the direction of the test stimulus. Instead, this task seems to involve a memory-scanning process, in which list directions are searched until the test one is identified and the next one in the sequence selected. This kind of process was suggested by the results of early experiments in the visual domain (Sternberg, 1969) and by those of later experiments in the motor

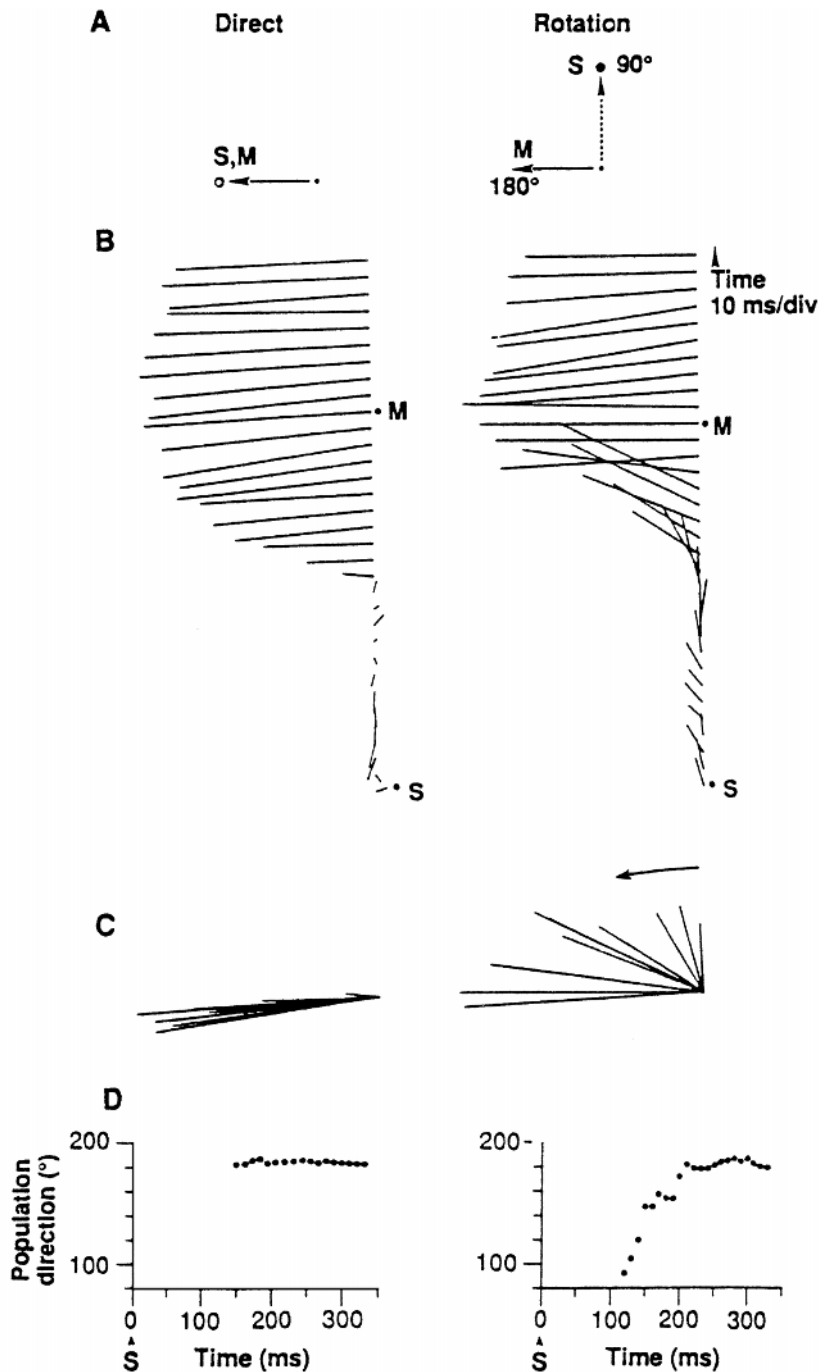

FIGURE 37.7 Results from a “direct” (left) and “rotation” (right) movement. (A) Task. Unfilled and filled circles indicate dim and bright light, respectively. Interrupted and continuous lines with arrows indicate stimulus (S) and movement (M) direction, respectively. (B) Neuronal population vectors calculated every 10 ms from the onset of the stimulus, S , at positions shown in (A) until after the onset of the movement, M . When the population vector lengthens, for the direct case (left) it points in the direction of the movement, whereas for the rotation case it points initially in the direction of the stimulus and then rotates counterclockwise (from 12 o’clock to 9 o’clock) and points in the direction of the movement. (C) Ten successive population vectors from (B) are shown in a spatial plot,

starting from the first population vector that increased significantly in length. Notice the counterclockwise rotation of the population vector (right). (D) Scatter plots of the direction of the population vector as a function of time, starting from the first population vector that increased significantly in length following stimulus onset (S). For the direct case (left), the direction of the population vector is in the direction of the movement ($\sim 180^\circ$); for the rotation case (right), the direction of the population vector rotates counterclockwise from the direction of the stimulus ($\sim 90^\circ$) to the direction of the movement ($\sim 180^\circ$). (From Georgopoulos et al., 1989. Reproduced with permission of the publisher. Copyright AAAS, 1989.)

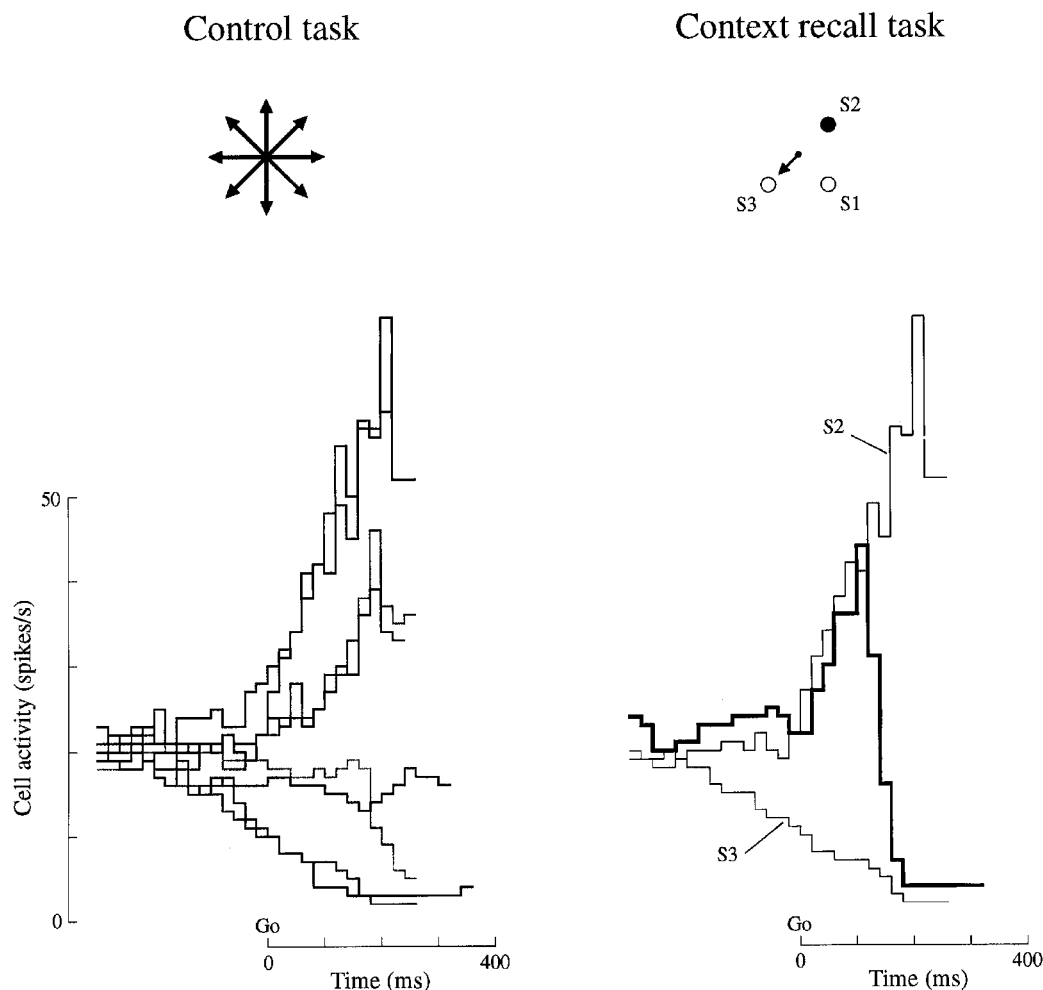

FIGURE 37.8 Peristimulus histograms of activity of a motor cortical cell are shown for eight directions in the control task (left), and one case of the context-recall task (right). In the left panel, histograms of cell activity are color coded for motor responses in different directions in the control task. In the right panel, two of these histograms are reproduced as thinner lines together with the histogram (black) of cell activity in the con-

dition of the context-recall task illustrated on the top. After the go signal, cell activity (black) initially increased in the same way as in the control case (thin red line) for the direction toward the test stimulus (S_2) and then changed abruptly and decreased to the level corresponding to the control activity for the direction of the motor response (toward S_3). (From Pellizzer, Sargent, and Georgopoulos, 1995.)

field (Georgopoulos and Lurito, 1991); namely, that the response time increases as a linear function of the number of list stimuli. Indeed, this relation also was present in the monkey performance (Carpenter, Pellizzer, and Georgopoulos, 1996). The question, then, is what are the neural mechanisms of this memory scanning process? The results of neurophysiological studies in the motor cortex (Pellizzer, Sargent, and Georgopoulos, 1995) showed that the basic element of these mechanisms involves an abrupt (~ 40 ms) switching between the directions being searched. This was evident both at the single-cell and population levels. Specifically, single cells showed an abrupt change in activity from the pattern associated with the direction of test stimulus to that

associated with the direction of the motor response; an example is shown in figure 37.8 (see also color plate 23). At the ensemble level, the neuronal population vector switch abruptly from test to the motor direction. The difference between the neural mechanisms of this task and that of mental rotation was exemplified further by analyzing the activity of cells with preferred directions intermediate between the stimulus and the movement. As discussed in the preceding section, these cells were recruited selectively during the response time in the mental rotation task. In contrast, they were not engaged in the memory-scanning task. This is shown in figure 37.9. Therefore, the mental rotation and memory-scanning tasks involve fundamentally different kinds of

FIGURE 37.9 Peristimulus time histograms (10 ms binwidth) of the activity of cells with preferred direction at the intermediate direction ($\pm 10^\circ$) between the stimulus and movement directions in the mental rotation task (2,3), and between the test stimulus (S_2) and motor response (S_3) in the context-recall task (19). Histograms start at the onset of the go signal (time zero). In the mental rotation task, the activity of such cells (thin line) increased by more than threefold and was statistically sig-

nificant (indicated by *), whereas in the context-recall task, cell activity remained almost constant (thick line) and was not statistically significant compared with cell activity during the first 80 ms (dotted line; *baseline period*) (20). The arrows indicate the average time (\pm SD) at which the population vector began to change direction (*Begin*) and when it attained the direction of the motor response (*End*). (From Pelizzier, Sargent, and Georgopoulos, 1995.)

mechanisms (slow rotation vs. abrupt switching) both of which were identified, remarkably, within the same (proximal arm) area of the motor cortex.

Conclusions

Our studies of the motor mental rotation and memory-scanning tasks using both fMRI and single-cell recordings provide a useful ground for trying to define the boundaries of the gain in knowledge provided by these methods. The neurophysiological studies showed clearly that the motor cortex is involved in both of these tasks, and this also was documented by the fMRI studies. Therefore, there is an excellent correspondence between the two methods regarding this point. Because of the kind of fMRI signal, this is as far as the fMRI studies can go: they cannot provide information concerning the nature of the cellular information processing mechanisms involved. These can be glimpsed at from the results of the neurophysiological studies. These results demonstrate clearly that the neural mechanisms both at the single cell and at the population levels are very different in the two cases. Of course, no neuroimaging study could have distinguished between these two different mechanisms. This consideration brings forward an important point, namely that the “activation” of an area

needs to be considered cautiously, within the context of other information gained from studies using different methods. Conversely, no single-cell recording study could have produced the “bird’s eye” view provided by the fMRI study and the insight provided by the MDS analysis, in regard to both the task dimensions and the differential involvement of brain areas with information processing along these dimensions. Neurophysiological studies are appropriate for examining in depth the cellular mechanisms but not the overall activation patterns. Therefore, the two methods are complementary and together can provide a more integrated view of the neural mechanisms of behavior.

38 Cortical Mechanisms Subservicing Object Grasping and Action Recognition: A New View on the Cortical Motor Functions

GIACOMO RIZZOLATTI, LEONARDO FOGASSI, AND VITTORIO GALLESE

ABSTRACT This chapter provides evidence for a new and broader view of the functions of the cortical motor system. On the basis of the functional properties of a monkey premotor area (area F5), the authors propose that at the core of the cortical motor systems there are vocabularies of motor actions. Neurons forming these vocabularies store knowledge about actions and the description of how this knowledge must be applied. When a specific population of these neurons becomes active, an internal copy of a specific action is generated. This copy may be used for two purposes: (1) planning and executing goal-directed actions or (2) recognizing actions made by another individual. The action recognition is based on a match between an observed action and its internal motor copy. Finally, evidence is reviewed showing that an action observation/execution matching system, similar to that of the monkey, also is present in humans.

“The motor systems of the brain exist to translate thought, sensation and emotion into movement. At present the initial steps of this process lie beyond analysis. We do not know how voluntary movements are engendered, nor where the ‘orders’ come from” (Henneman, 1984). This sentence, which starts the section on the organization of the motor system in the classic *Medical Physiology*, edited by Mountcastle, expresses well the prevalent ideas about the motor system: The motor system deals with *movements*. The processes that lead to them are remote processes virtually inaccessible to neurophysiologic inquiry.

The view proposed in this chapter is different. First, we challenge the view that *movement* is at the core of the motor system. *Action* is. Unlike movement, action is defined by a goal and by an expectancy. Movements are the final outcome of action and are programmed and controlled as such only when action is set and executed.

Second, motor system is involved not exclusively in action generation but also plays an important role in matching the external reality on the internally produced actions. We submit that in primates, this second role is by no means secondary but has a great importance for recognizing actions made by others.

Although we believe that these concepts are valid in general for the mosaic of motor areas forming the agranular frontal cortex, in this chapter, we use as an example the organization of one monkey premotor area, area F5. In this area, the two aspects of the motor system, action generation and action recognition, clearly emerge.

Motor properties of F5 neurons

Figure 38.1 shows a lateral view of the monkey brain. Area F5 forms the rostral part of inferior area 6. It is located anterior to area F4 and extends into the posterior bank of the inferior arcuate sulcus (Matelli, Luppino, and Rizzolatti, 1985).

Area F5 is not homogeneous. At least two morphologically distinct sectors can be distinguished in it, F5 of the convexity (F5c) and F5 forming the posterior bank of the arcuate sulcus (F5ab) (Matelli et al., 1996). Corticospinal fibers originate from F5ab only (He, Dum, and Strick, 1993).

Intracortical microstimulation studies and neuron recordings showed that area F5 is involved in the control of hand and mouth movements. (Rizzolatti et al., 1981a, 1981b; Kurata and Tanji, 1986; Gentilucci et al., 1988; Rizzolatti et al., 1988; Hepp-Reymond et al., 1994). Although there is a considerable overlap between the two representations, hand movements are located more dorsally, whereas mouth movements are located more ventrally (Gentilucci et al., 1988).

Particularly important for understanding the function of F5 are the results obtained by testing F5 neurons in a

GIACOMO RIZZOLATTI, LEONARDO FOGASSI, and VITTORIO GALLESE Istituto di Fisiologia Umana, Università di Parma, Parma, Italy

FIGURE 38.1 Lateral view of macaque monkey cerebral cortex showing frontal and parietal areas. The intraparietal sulcus is opened to show areas located in its medial and lateral banks. Frontal agranular cortical areas are classified according to Mattelli et al. (1985). The cortical areas of the parietal convexity are classified according to Von Bonin and Bailey (1947). Abbreviations: AIP, anterior intraparietal area; LIP, lateral intraparietal area; MIP, medial intraparietal area; VIP, ventral intraparietal area.

naturalistic context (Rizzolatti et al., 1988). Awake monkeys were seated on a primate chair and presented with various objects (geometric solids, pieces of food of different size and shape). The stimuli were introduced in various spatial locations around the monkey, inside and outside its peripersonal space. After object presentation, the monkey was allowed to reach and grasp the objects.

The results confirmed that most neurons become active in relation to distal movements. However, they also showed that the neuron discharge typically correlates much better with an action or with fragments of an action (motor acts) rather than with the movements forming it. Thus, many neurons discharge when an action (e.g., grasping) is performed with effectors as different as the right hand, the left hand, or the mouth. An example of this behavior is shown in figure 38.2. Furthermore, in most neurons, the same type of movement (e.g., an index finger flexion) effective in triggering a neuron during grasping made with the index finger and the thumb was not effective during grasping made using all fingers. Thus, in these cases, the characterization of neuron activity in terms of individual movements is meaningless.

By using actions as classification criteria, F5 neurons were subdivided into the following main categories: grasping-with-the-hand-and-the-mouth neurons, grasping-with-the-hand neurons, holding neurons, tearing neurons, poking neurons, and manipulating neurons. Grasping neurons were the neuron type most represented (Rizzolatti et al., 1988).

Grasping is a complex action characterized by an initial opening phase, during which fingers are shaped according to the object physical properties (size, shape) and the wrist is adapted to object orientation, and a second, closure phase, in which fingers are flexed around the object until they touch it (Jeannerod, 1988). The type of hand shape depends on the size and shape of the object to be grasped. The three grip types that monkeys most frequently use are: precision grip, which is opposition of the thumb to the index finger (used for grasping small objects); finger prehension, which is opposition of the thumb to the other fingers (used to grasp middle-sized objects or to retrieve them from a narrow container); and whole-hand (or power) prehension, which is opposition of the fingers to the palm (used to grasp large objects). Neurons were recorded while monkeys grasped objects using these three grip types.

The results showed that most (85%) grasping neurons are selective for one of the three main grip types. The most represented type is precision grip, the least represented is whole-hand prehension. There is specificity for different finger configurations even within the same general type of grip. Thus, for example, in the case of whole-hand prehension, the prehension of a sphere, which requires the opposition of all fingers, is encoded by different neurons than the prehension of a cylinder, for which a palm opposition grip, thumb excluded, is required (figure 38.3).

Both neurons selective for a specific grip type and those unspecific showed a variety of temporal relations with the prehension phases. Some F5 neurons discharged during the whole action coded by them, sometimes starting to fire at stimulus presentation. Some were active mostly during the opening of the fingers, some during finger closure (Jeannerod et al., 1995).

A METHODOLOGICAL INTERLUDE Before discussing the theoretical importance of these findings, a methodological point must be stressed. Typically, in neuron studies of the motor cortex, the behavioral or ethological context in which movements are emitted are considered of little or no importance. The variable that is controlled is movement. Paradigmatic in this sense are the experiments of Evarts, in which the animal had simply to move the wrist or exert a force (Evarts, 1981).

Had this approach been used in the study of F5, the most important characteristics of its neurons would have been lost. For example, it would have been impossible to discover that that same neuron discharges during mouth grasping and hand grasping. Similarly, because many grasping neurons produce a weak response during an inappropriate movement (e.g., a finger flexion), their

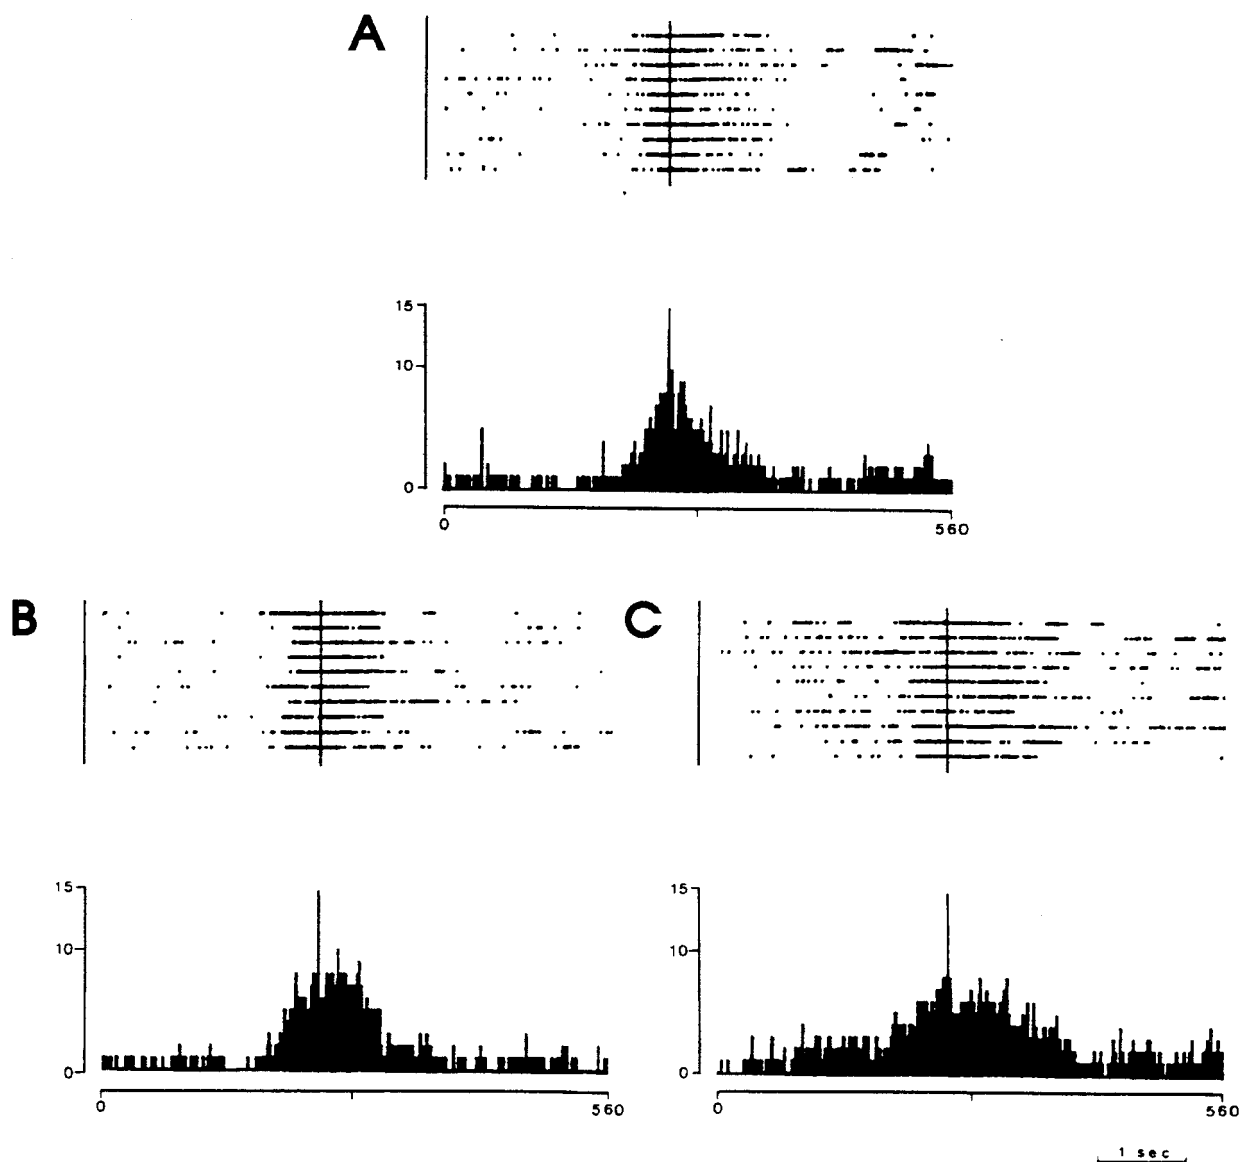

FIGURE 38.2 Example of a “grasping-with-the-hand-and-the-mouth” F5 neuron. (A) Neuron discharge during grasping with the mouth. (B) Neuron discharge during grasping with the hand contralateral to the recorded hemisphere. (C) Neuron discharge during grasping with the hand ipsilateral to the re-

corded hemisphere. Rasters and histograms are aligned with the moment in which the monkey touched the food. The histograms are the sum of ten trials. Abscissae: time expressed in bins. Bin width: 10 ms. Ordinates: spikes/bin. (Modified from Rizzolatti et al., 1988.)

main characteristic (e.g., that of firing during specific motor action) also would have passed unnoticed.

The results of F5 study indicate that for cortical motor neurons, the same strategy should be used as that so successfully adopted in the sensory systems. For each neuron, the specific motor triggering feature must be established, and for those responding to passive stimuli, the sensory triggering features also must be assessed. Only, at this point, specific behavioral tasks can be adopted. Without such a strategy, one would never

“know how voluntary movements are engendered, nor where the ‘orders’ come from.”

A “VOCABULARY” OF MOTOR ACTION Some years ago, Arbib (1981) proposed to describe the behavior of individuals in terms of schemas. A schema is both a store of knowledge and the description of a process for applying that knowledge. The schema idea can be applied at the single neuron level. The properties of F5 neurons fit this definition. These neurons store specific

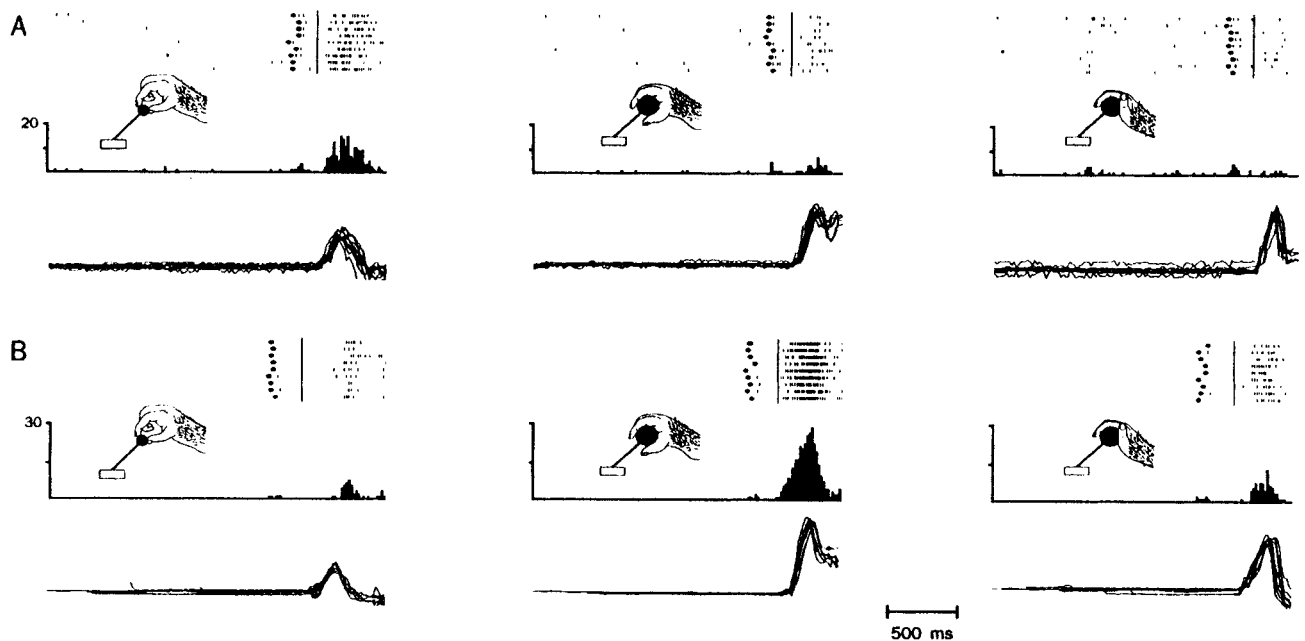

FIGURE 38.3 Examples of two F5 “grasping-with-the-hand” purely motor neurons. Recordings were made during the following behavioral task; the monkey was seated in front of a dark box. Trials began when the monkey pressed a keypad. Pressing the keypad illuminated the box, and a geometric solid located inside of it became visible. After a variable delay, the front door of the box opened, allowing the monkey to reach for and grasp the object. (A) Neuron selective for precision grip. (B) Neuron selective for whole-hand prehension. Rasters

and histograms and the distance between the thumb and the index finger (recorded with a computerized movement analyzer) are shown, aligned with the onset of hand movement (vertical bar). Dots indicate the opening of the box front door. The grasped objects were, from left to right: a small sphere, a large sphere, and a horizontally oriented cylinder. Abscissae: time expressed in ms; ordinates: spikes/bin. Bin width: 20 ms. (Modified from Jeannerod et al., 1995.)

knowledge about an action and, when activated, indicate how to implement it.

F5 is a store of motor schemas or, using the terminology of Rizzolatti (Rizzolatti and Gentilucci, 1988; Gentilucci and Rizzolatti, 1990) a “vocabulary” of actions. This motor vocabulary is constituted by “words,” each of which is represented by a set of F5 neurons. Some words indicate the general goal of an action (e.g., grasping, holding, tearing); others indicate the way in which a specific action must be executed (e.g., precision grip or finger prehension). Finally, other words are concerned with the temporal segmentation of the action into motor acts, each coding a specific phase of the grip (e.g., hand opening, hand closure).

The view that F5 contains a vocabulary of motor schemas has important functional implications. First, the presence of such a vocabulary strongly facilitates the execution of motor commands. The existence of neurons, which represent specific motor schemas and are anatomically linked (hard-wired) with cortical (F1) and subcortical motor centers, facilitates the selection of the most appropriate combination of movements by reducing the number of variables that the motor system has to control to achieve the action goal. Second, it simplifies

the association between a given stimulus (i.e., a visually presented object) and the appropriate motor response toward it. Third, it gives the brain a storage of motor schemas (i.e., a knowledge about actions) that, as we show in the next sections, provides the motor system with functions traditionally attributed to the sensory systems.

Canonical F5 neurons

The motor properties of F5 we described in the previous section are proper to all F5 neurons. Studies of the responsiveness of F5 neurons have shown that many of them respond to visual stimuli. According to the type of effective visual stimulus, the responsive neurons (visuomotor neurons) were subdivided into two main categories. Neurons of the first category discharge when the monkey observes graspable objects. As evident in a forthcoming section, these neurons play a role in object-to-hand movement transformations. Because visuomotor transformation is a function traditionally attributed to the ventral premotor cortex, we refer to them as “canonical” F5 neurons. Neurons of the second category discharge when the monkey observes another individual making an

action in front of it. We refer to these neurons as “mirror neurons” (Gallese et al., 1996; Rizzolatti et al., 1996a).

The two categories of F5 neurons are located in two different subregions of area F5: canonical neurons are found mainly in F5ab, whereas mirror neurons are recorded almost exclusively from the cortical convexity (F5c).

VISUAL PROPERTIES OF CANONICAL F5 NEURONS Experiments in which F5 neurons were tested using natural stimuli showed that many F5 neurons became active in response to object presentation (Rizzolatti et al., 1988). Recently (Murata et al., 1997), the visual responses of F5 neurons to object presentation were re-examined using a formal behavioral paradigm originally devised by Sakata (Murata et al., 1996). The paradigm was basically as follows.

The monkey faced a dark box where geometric objects (e.g., cube, cylinder, sphere) of different size and shape were located. The objects were presented one at a time. The trial started with the presentation of a colored spot of light on the object that remained invisible. At the spot presentation, the monkey had to fixate it and press a bar. The bar pressing illuminated the box and made the object visible. After a variable delay, the spot changed color. This was the signal for the monkey to release the bar and reach and grasp the object (“grasping in light” condition). In a second condition, all the events were as aforementioned, but when the spot changed color, the monkey had only to release the bar. Object grasping was not allowed (“object fixation” condition). The two conditions were run in different blocks, and the spot colors in them were different. In a third condition (“grasping in dark” condition), the same object was presented for many consecutive trials. The monkey saw the object before the beginning of the first experimental trial, and therefore knew its characteristics, but it had to perform the entire task without visual guidance. Eye movements were controlled in all conditions.

The results showed that approximately half of the tested neurons responded to three-dimensional (3-D) object presentation and two thirds of them were selective to one specific object or to a cluster of objects. A strict congruence between visual and motor selectivity was found in most recorded neurons. Figure 38.4 shows the responses of a visually selective neuron. Observation and grasping of the ring produced strong responses (figure 38.4A). Responses to the other five objects were modest (sphere) or virtually absent.

Figures 38.4B and C show the behavior of the same neuron in two other experimental conditions: object fixation and object grasping in dark. In the object fixation condition, the objects were presented as aforementioned,

but at the go signal, instead of grasping the object, the monkey had to release a key. Grasping was not allowed. In this condition, the object is totally irrelevant for task solution, which only requires the detection of the go signal (spot color change). However, the neuron strongly discharged at the presentation of the preferred object (figure 38.4B).

The behavior of the neuron during object grasping in dark is illustrated in figure 38.4C. In the absence of any visual stimulus, the neuron discharged in association with ring grasping. The movement-related discharge was preceded by a sustained activity.

How can these findings be explained? At the onset, the object related visual responses could not be attributed to unspecific factors, such as attention or “intention” (desire to grasp the object). If either of these possibilities were true, the neuron would have not shown object specificity. Attention and “intention” are the same, regardless of which is the object presented. How can the neuron response to the object be interpreted?

Before answering this question, we must consider that a discharge extracellularly recorded from a neuron represents the output of this neuron regardless of how the neuron is excited. Thus, the responses of a given F5 neuron must be either visual, with the responses reflecting the physical aspect of the object, or motor, dealing with the activation of a motor schema—that is, the “idea” of how a motor effector must interact with the object.

The fact that F5 is a premotor area suggests that the object-related F5 neurons responses should represent objects in motor terms. Every time an object is presented, it triggers an immediate retrieval of the specific word of the motor vocabulary related to that object. Therefore, regardless of any intention to move (see “object fixation condition”), the “visual” response to object presentation would be the translation of the object into a potential motor action. The representation of this potential action then is kept active during the period following object presentation (see the sustained response following object presentation) and is transformed in overt movement only when the response is allowed.

Preliminary experiments from our laboratory confirm this interpretation (see also Murata et al., 1997). A large number of visually responsive neurons discharge to the presentation of objects that, although differing in shape (i.e., cube, cone, sphere), nevertheless are grasped in the same way.

The AIP-F5 grasping circuit

VISUAL INPUT TO F5: AREA AIP Regardless of the interpretation of their discharge, there is no doubt that many F5 neurons respond to visual stimuli. Which is the

source of this input? For many years, it has been known that inferior area 6 is connected heavily with the inferior parietal lobe (Petrides and Pandya, 1984; Matelli et al., 1986; Cavada and Goldman-Rakic, 1989). More recently, Sakata and coworkers (Taira et al., 1990) showed that in the rostral half of the lateral bank of the intraparietal sulcus (IPS), there are neurons, located in a particular sector, that become active during hand actions. They called this sector *anterior intraparietal area*, or area AIP (Sakata et al., 1995). Anatomic experiments showed that AIP and F5 are strongly reciprocally connected (Matelli et al., 1994; Matelli and Luppino, 1997).

The properties of AIP neurons have been studied by Sakata and associates (1995) using a paradigm similar to that used for F5 neurons. Neurons active during the task were subdivided into three classes: motor dominant neurons, visual and motor neurons, and visual dominant neurons. Two of them—motor dominant neurons and vi-

sual and motor neurons—have discharge properties similar to those of motor and visuomotor F5 neurons, respectively, whereas the third class—visual dominant neurons—is not present in F5. Visual dominant neurons are active during object fixation and grasping movements executed under visual guidance, but they do not respond when the same movements are executed in darkness (Sakata et al., 1995).

Like F5 neurons, many AIP neurons are selective for object shape and size. Among those classified as visual and motor neurons, many show the same selectivity during both object fixation and object grasping.

Although F5 and AIP share many common features, there also are some differences between them. In particular: (1) visual responses to 3-D objects are observed more frequently in AIP than in F5; (2) virtually all F5 neurons have motor properties, whereas these properties are present only in a set of AIP neu-

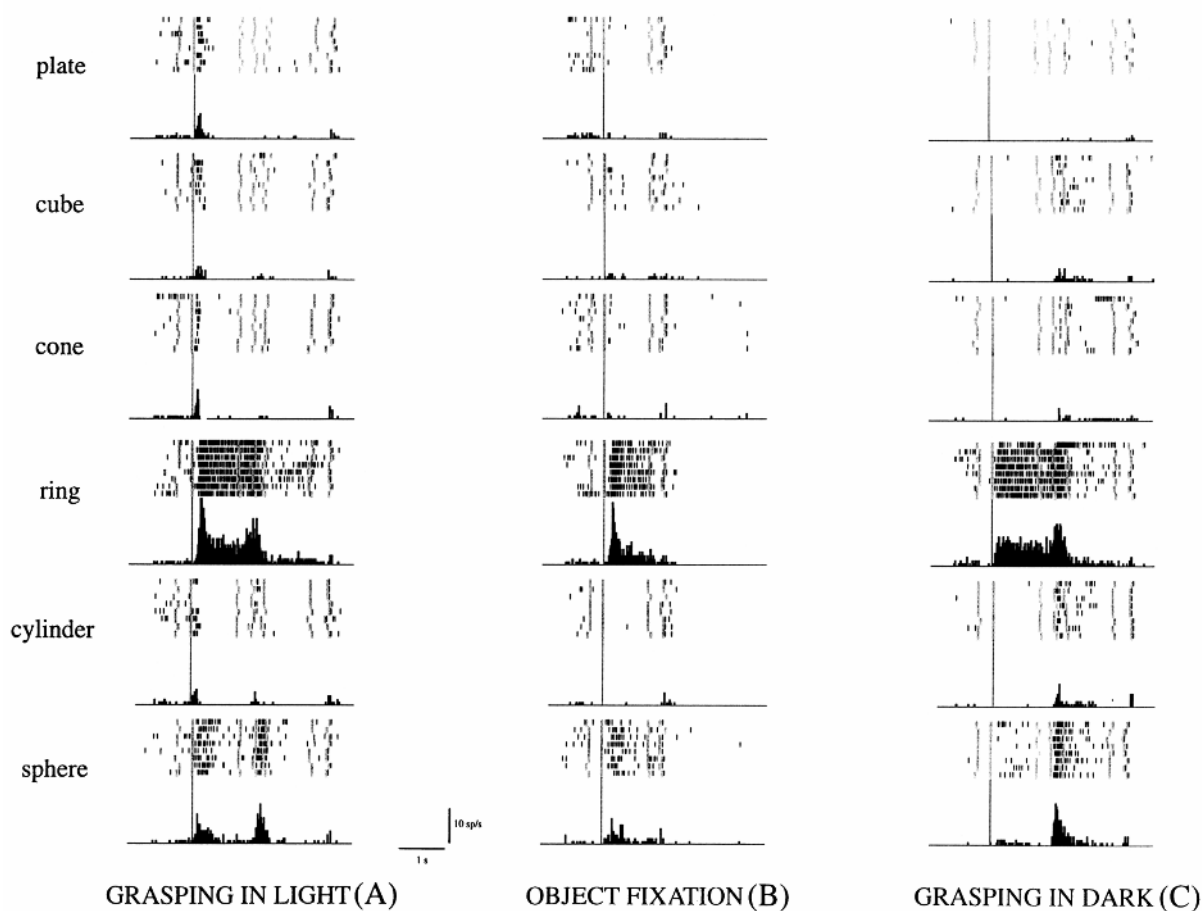

FIGURE 38.4 Example of a F5 “grasping-with-the-hand” visuomotor neuron. Panels show neural activity recorded during three different experimental conditions (A–C). Rasters and histograms are aligned (vertical bar) with key press. In (A) and (B), key press determines the illumination of the object. Small gray bars in each raster of (A) and (C) indicate, from left to right: appearance of a spot of light on the object; key press;

change of color of the spot; key release; onset of object pulling; further change of color of the spot; onset of object release. Small gray bars in each raster of (B) indicate, from left to right: appearance of a spot of light on the object; key press; change of color of the spot; key release. Abscissae: time expressed in s. Ordinates: spikes/s. (Modified from Murata et al., 1997.)

Control

Muscimol (site B)

FIGURE 38.5 Preshaping and actual grasping of a small plate in a groove. *Top row:* single frame images redrawn from video and stick diagram of a typical control trial. During preshaping, the monkey extends its index finger and simultaneously flexes the last three fingers. Actual grasping is achieved by opposing the thumb and the index finger (precision grip). *Bottom row:*

single frame images redrawn from video and stick diagram of a single trial performed after muscimol microinjection in area AIP. During preshaping, flexion of the last three fingers did not occur, and thumb–index finger opposition could not be executed. (Modified from Gallese et al., 1994.)

rons; (3) visual dominant neurons are present only in AIP; and (4) most AIP neurons discharge during the whole grasping action, whereas this occurs only in some F5 neurons, F5 neurons discharging more frequently only in some of the phases in which grasping is subdivided.

INACTIVATION STUDIES The data discussed thus far strongly suggest that the AIP-F5 circuit is involved in visuomotor transformations for grasping. This role of the AIP-F5 circuit recently was proved directly by inactivation data.

The effect of inactivation of AIP (muscimol injections) on grasping behavior was studied by Gallese and colleagues (1994). They trained a monkey to reach for and grasp geometric solids of different size and shape, each of which required a specific pattern of finger movements to be grasped adequately.

After muscimol injection, the behavior of the hand contralateral to the injection side was markedly impaired. Severe disruption of preshaping of the hand was observed constantly. As a consequence, there was a mismatch between the 3-D features of the objects to be grasped, especially of the small ones, and the posturing of finger movements, leading either to a complete failure of prehension or to an awkward grasping. In the case of

successful grasping, the grip very often was achieved after several correction movements that relied on tactile exploration of the object. A deficit in reaching never was observed.

Figure 38.5 illustrates the grip of a small plate positioned in a groove performed before (upper part) and after (lower part) AIP inactivation. After inactivation, hand preshaping was disrupted completely; the monkey did not flex its last three fingers and very often failed to insert the index finger into the groove. When the monkey occasionally succeeded in inserting it, it nevertheless was unable to oppose the finger to the thumb.

Preliminary experiments in which muscimol was injected into F5ab—that is, in the F5 sector in which canonical neurons are located—produced similar deficits. The impairment was limited to precision grip of the hand contralateral to the lesion when small injections were made. Larger injections produced bilateral deficit concerning all grip types (Gallese et al., 1997).

VISUOMOTOR TRANSFORMATION FOR GRASPING: A POSSIBLE NEURAL MODEL The functional properties of F5 and AIP just reviewed allow one to propose a model that can explain how the AIP-F5 circuit transforms visual information into action. Mainly, the AIP visual

FIGURE 38.6 Cartoon schematically representing a model of AIP-F5 interactions for hand grasping under visual guidance. The figure shows an object that may be grasped in various ways. The object is analyzed by the posterior part of the infe-

rior parietal cortex (cIPS area) and by AIP. The selection of prehension type occurs in area F5. (Modified from Fagg and Arbib, 1998.)

dominant neurons receive information on object properties from 3-D object sensitive neurons located in an area posterior to LIP, called caudal IPS (cIPS, see Shikata et al., 1996). The AIP neurons extract from this global object description some specific aspects. For example, in the case of the mug shown in figure 38.6, AIP neurons respond to the handle of the mug, to its body, or its body upper border. Therefore, they parcellate the global object into its parts. This multiple description then is sent to F5, “proposing” various grasping possibilities. One of them is chosen. The choice depends on the concomitant information (purpose of the grasping, internal drive, spatial relationship with other objects) that F5 receives from the prefrontal lobe by means of other premotor areas or directly. On the basis of joint AIP input and visual and nonvisual contextual information, a grasping schema (e.g., precision grip) is selected. This schema then (1) is sent back to AIP by way of motor dominant neurons, allowing matching between the selected movement pattern and the visual input during action execution and (2) activates in sequence the various motor act schemas forming the grasping actions (e.g., hand opening, hand closure). These motor act schemas provide the necessary information to F1 and subcortical centers for action execution. A computational model of the AIP-F5 circuit based on principles similar to those just described recently was proposed by Fagg and Arbib (1998; Fagg, 1996).

Mirror F5 neurons

In addition to canonical neurons, in F5, there is a second category of visuomotor neurons. These neurons become active both when the monkey performs an action *and* when it observes a similar action made by another monkey or by the experimenter. The presentation of 3-D objects, even when held by the hand, does not evoke the neuron discharge. These neurons have been named “mirror neurons” (Gallese et al., 1996; Rizzolatti et al., 1996a). An example is shown in figure 38.7.

To discover the trigger features of mirror neurons, Rizzolatti and coworkers (1996a; Gallese et al., 1996) presented the monkey with a series of actions. They were transitive actions (such as grasping, holding, manipulating, or tearing objects), intransitive movements with emotional content (e.g., threatening gestures) or without it (e.g., arms lifting). Furthermore, to control whether a recorded neuron responded specifically to hand-objects interactions, the following actions also were performed: hand movements mimicking object-related actions in the absence of the objects; prehension movements made using tools such as pincers or pliers; simultaneous movements of hands and objects kept spatially separated. Finally, to rule out the possibility that mirror neurons activation could be due to unspecific factors such as food expectancy or motor preparation for food retrieval or reward, a group of neurons were stud-

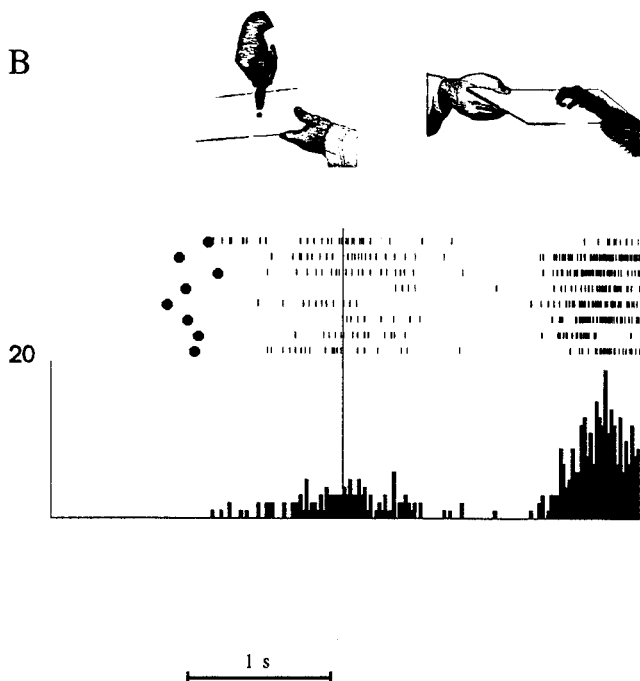

FIGURE 38.7 Example of the visual and motor responses of an F5 mirror neuron. The behavioral situations during which the neural activity was recorded are illustrated schematically above rasters. (A) A tray with a piece of food placed on it was presented to the monkey; the experimenter made the grasping movement toward the food and then moved the tray with the food toward the monkey, which grasped it. The neural discharge was absent when the food was presented and moved toward the monkey. In contrast, a strong activation was present during grasping movements of both the experimenter and the monkey. (B) As in (A), except that the experimenter grasped the food with pliers. Note the much weaker response when the observed grasping was performed with a tool. Rasters and histograms are aligned (vertical bar) with the moment in which the experimenter touched the food. Dots indicate the beginning of the trials. Abscissae: time. Ordinates: spikes/bin. Bin width: 20 ms. (From Gallese et al., 1996.)

tions made using tools either did not activate the neurons or activated them only very weakly (see figure 38.7).

The observed hand actions most effective in triggering the neurons were grasping, manipulating, and placing. More than half of neurons, among those activated by the observation of hand action, were active during the observation of one action only. The remainders responded to two or, rarely, three of them. Some neurons were selective not only to the general action aim (e.g., grasping) but also to how the action was performed, selectively firing during the observation of one particular type of grip (e.g., precision grip, but not whole-hand prehension).

There was a large amount of generalization in terms of the precise physical aspects of the effective agent. For many neurons, the precise hand orientation was not crucial for activation. Similarly, in most cases, the distance from the monkey at which the action was executed did not influence the response. For most neurons, the effect was the same when the experimenter used the right or the left hand. In one third of tested neurons, however, the discharge consistently was stronger when the action was made by one hand instead of the other.

As far as the objects targets of the observed action are concerned, their significance for the monkey did not influence the neuron discharge. The responses to meaningful objects like food were the same as those to 3-D solids. The sizes of the objects, target of the action, were relevant in one third of the recorded neurons. In these cases, neurons were visually activated only when the object of the effective observed action had a specific size. The selectivity was related to the real size of the object and not to its size on the retina. It is likely, however, that this selectivity was not due to the visual characteristics of the objects, but to the grip that their size evokes. Experiments to dissociate these two variables have not been carried out yet.

ied using a second monkey as the agent of the action. Although the second monkey grasped food and ate it, the first monkey (the monkey from which neurons were recorded) observed its action passively.

MIRROR NEURONS PROPERTIES The visual stimuli most effective in triggering mirror neurons were found to be actions in which an agent (another monkey or an experimenter) interacts with an object using either the hand or, more rarely, the mouth. Object presentation, including interesting stimuli such as food items or the sight of faces or body movements were ineffective. Similarly, ac-

FIGURE 38.8 Example of the visual and motor responses of a highly congruent F5 mirror neuron. The behavioral situations during which the neural activity was recorded are illustrated schematically above neural records. Four continuous recordings are shown in each panel. (A) The monkey observes the experimenter rotating his hands around a small piece of food in opposite directions, alternating clockwise and counterclockwise movements. The response is present only in one rotation direction. (B) The experimenter rotates a piece of food held by the monkey, which opposes the experimenter movement by rotating its wrist in the opposite direction. (C) The monkey grasps a piece of food using a precision grip. Small arrows above the records in (A) and (B) indicate the rotations direction. (From Rizzolatti et al., 1996a.)

precision grip). For other neurons, the congruence was broader. For them, the motor requirements (e.g., precision grip) usually were more strict than the visual ones (any type of hand grasping). An example of a highly congruent mirror neuron is shown in figure 38.8.

OTHER AREAS RESPONDING SELECTIVELY TO BIOLOGICAL STIMULI Neurons responding to complex biological stimuli had been described previously in the macaque brain. A series of studies showed that neurons that discharge selectively to the presentation of faces or hands are present in the inferotemporal lobe (Gross, Rocha-Miranda, and Bender, 1972; Perrett, Rolls, and Caan, 1982; Desimone et al., 1984; Rodman, O'Scalaidhe, and Gross, 1993) and in the prefrontal lobe below the principal sulcus (Pigarev, Rizzolatti, and Scandolara, 1979; O'Scalaidhe, Wilson, and Goldman-Rakic, 1997). Neurons responding to complex biological visual stimuli such as walking or climbing also were reported in the amygdala (Brothers, Ring, and Kling, 1990). Even more relevant to the present issue is the work of Perrett and co-workers (Perrett, Rolls, and Caan, 1982; Perrett et al., 1989, 1990). These authors showed that in the lower bank of the superior temporal sulcus (STS), there are neurons selectively activated by the observation of hand-object interactions. These properties resemble the visual properties of F5 mirror neurons: both STS and F5 mirror neurons code the same types of actions; they both generalize their responses to the different instances of the same action; and neither are responsive to mimicked hand actions without the target object. However, the distinctive feature of F5 neurons—and, so far, their uniqueness—resides in the fact that they discharge also during active movements of the observer: an observed action and action actively made produce the same neural pattern of activation.

The presence of two brain regions, neurons of which are endowed with similar visual properties, raises the question of their possible relationship. A possibility is

Mirror neurons, like canonical neurons, discharged during active movements. A comparison between the actions they code and the actions that trigger them when seen showed that for almost all the mirror neurons, there was a clear congruence between the observed and executed action. This congruence was for many neurons extremely strict, that is, the effective motor action (e.g., precision grip) coincided with the action that, when seen, triggered the neurons (e.g., again,

that STS and F5 represent distinct stages of the same system. The STS neurons provide an initial "pictorial" description of an action that is then fed (through an intermediate step in the posterior parietal cortex or in the prefrontal lobe) to area F5, where this description is matched with the pattern responsible for the execution of the same action.

THE MIRROR SYSTEM IN HUMANS The first evidence that a mirror system exists in humans was provided by Fadiga and associates (1995), who stimulated the motor cortex of normal human subjects using transcranial magnetic stimulation (TMS). The rationale of the experiment was the following. If the observation of an action activates the premotor cortex in humans, as it does in monkeys, then TMS should induce, during action observation, an enhancement of motor-evoked potentials (MEPs) recorded from the muscles that are active when the observed action is executed. The results confirmed the hypothesis. During the observation of grasping movements, a selective increase of MEPs was observed in the muscles that the subjects used for grasping objects.

Although these data indicate that an action execution/observation matching system exists in humans, they do not give information on the circuits underlying it. Data on this issue were provided by two positron-emission tomography (PET) experiments (Rizzolatti et al., 1996b; Grafton et al. 1996) and, more recently, by a neuromagnetic study (Hari et al., 1998). The two PET experiments differed in many aspects, but both had a condition in which subjects observed the experimenter grasping an object. In this condition, there was an activation of the STS, the inferior parietal lobule, and the inferior frontal gyrus (area 45). All activations were in the left hemisphere. The neuromagnetic study (Hari et al., 1998) was focused on the precentral motor cortex, the basic rhythm of which desynchronizes during active hand movements (Salenius et al., 1997). The results showed that grasping observation produced a similar desynchronization in the absence of any movement. The grasping observation-related desynchronization most likely reflects an activation of motor cortex due to an input to it coming from the inferior frontal gyrus or other premotor areas. The alternative interpretation, that mirror neurons also are present in the precentral motor cortex, is rather unlikely considering their absence in monkey area F1 (area 4) (Gallese et al., 1996).

Thus, the cortical areas active during action observation in humans match well those active in the monkey in the same conditions. In addition to the aforementioned areas containing neurons responding to meaningful biological stimuli, preliminary evidence from our laboratory shows that mirror neurons are present in inferior

parietal cortex (Fogassi et al., 1998). Note also that there is a growing consensus that F5 is the monkey homologue of Broca's area, or of part of it (Von Bonin and Bailey, 1947; Petrides and Pandya, 1994; Preuss, Stepniewska, and Kaas, 1996; and Rizzolatti and Arbib, 1998).

Taken together, these data indicate that a system matching action observation and action execution is present in humans as in monkeys. This system includes frontal, parietal, and temporal lobe areas.

POSSIBLE FUNCTION OF MIRROR NEURONS Primates are social animals living in continuous mutual relationship with conspecifics. Macaque monkeys live in groups characterized by active and intense social interactions, such as parental care, mating, and grooming that usually are disciplined by a well-delineated hierarchical organization. Therefore, it is crucial for each member of a given social group to be able to recognize the presence of another individual performing an action, to discriminate the observed action from others, and to "understand" the meaning of the observed action to react appropriately to it.

The observation of actions made by other individuals has another important function, that of learning their actions. When we learn a new motor skill, we observe and reproduce again and again the same sequence of actions that the teacher is displaying in front of us. The goal is to achieve as much as possible a match between the teacher-skilled motor behavior and our clumsy approximations of it. Evidence from developmental psychology demonstrates that in humans, the capacity to imitate is displayed soon after birth (Meltzoff and Moore, 1977). However, there is controversy about whether monkeys are able to learn by imitation; many authors maintain that a true learning by imitation is present, among primates, only in humans (see references in Galef, 1988; Whiten and Ham, 1992; Tomasello, Kruger, and Ratner, 1993; Byrne, 1995; Galef, 1998).

How do we recognize and imitate actions? One possibility is that action understanding and imitations require a complex cognitive description of the observed act. The existence of the mirror system suggests, however, another and simpler possibility. Everybody agrees that when an individual starts an action, he or she knows (predicts) its consequences. This knowledge is the result of an association between the schema of that action (the aforementioned potential action coded in the premotor cortex) and the consequences of this action. Thanks to mirror neurons, this knowledge can be extended to actions performed by others. When the observation of an action performed by another individual activates neurons that represent that action in the observer's premotor

cortex, the observed action is recognized because of the similarity (or even identity) of the evoked representation to that internally generated during its active programming.

Thus, we propose that the mirror system is a basic system for recognition of action. Both monkeys and humans use it for this purpose. In addition humans probably use this system also for action imitation (Jeannerod, 1994). If, as maintained by many, monkeys are unable to imitate actions made by other individuals, this would suggest that, although endowed of a mechanism that generates internal copies of actions made by others, they are unable to use them for replicating those actions. This would suggest that the intentional use of internal copies of actions developed only late in evolution.

Conclusions

What is the use of the motor system? The classical answer to this question is undoubtedly the one cited in the introductory section: "The motor system exists to translate thought, sensation and emotion into movement." The data reviewed in this chapter lead to a different and broader view. In primates, the aim of the motor system is to create internal copies of actions and to use these internal copies for generating actions as well as for understanding motor events.

According to this view, there are "vocabularies" of motor actions at the core of the cortical motor system. Neurons forming these "vocabularies" store both knowledge about an action and the description, at least in general (nonparametric) terms, of how this knowledge should be used. The ensemble of neurons related to a given action forms the global motor schema of that action. When an appropriate stimulus is presented, the relevant schema is activated. This does not imply that the action occurs any time a motor schema is activated. The activation of a motor schema determines only the appearance of an internal copy of that action that may be executed.

In the vocabulary of F5, there are two sets of visuomotor neurons: canonical neurons and mirror neurons. Canonical neurons together with neurons located in the parietal lobe area AIP form a circuit that transforms intrinsic object properties into hand action. They are automatically (regardless of animal intention to act) activated in response to appropriate stimulus presentation. The movements do not necessarily follow this activation. The way in which this internal copy, a potential action, is transformed into a real action currently is not known. Our suggestion is that the lateral parietofrontal circuits are under control of mesial motor areas (Rizzolatti et al., 1990; Rizzolatti, Luppino, and Matelli, 1996). Among

these, particularly suitable for this control role is area F6, which receives a massive input from prefrontal cortex (Luppino et al., 1993; Lu, Preston, and Strick, 1994). When internal and external contingencies are such that it is both desirable and feasible that a potential action becomes a real action, the control exerted by mesial areas is removed and the action may unroll.

From the existence of an internal copy of actions stems the second function of the motor system, that of matching an observed action onto the internal motor copy of the same action. The presence of a common code for a received message (in the case of mirror neurons, actions made by others) and for an action actively emitted by the observing individual gives a cue on how individuals can understand the "pictorial" description of the inferotemporal and parietal areas. The evidence we present concerns event recognition but it is likely that in early periods of life, the same mechanism is used also for giving meaning to other types of percepts (see Rizzolatti and Gallese, 1997). These considerations, although at the moment purely hypothetical, appear to be extremely fascinating because they open the possibility to approach neurophysiological issues that, like object semantics, were traditionally the domain of philosophical inquiry.

39 Neural Mechanisms for Learning of Sequential Procedures

O. HIKOSAKA, K. SAKAI, H. NAKAHARA, X. LU, S. MIYACHI, K. NAKAMURA,
AND M. K. RAND

ABSTRACT Acquisition of procedural skill requires long-term practice with repeated trial-and-error processes during which acquisition of knowledge (what to do) gradually is replaced with acquisition of skill (how to do). Using a visuomotor sequence task with trial-and-error processes for macaque monkeys and humans, the authors have shown that multiple brain areas contribute to different stages and different aspects of procedural learning. The frontal cortex (particularly the pre-supplementary motor area [SMA]) and the anterior part of the basal ganglia contribute to the initial stage of learning, in which knowledge for the procedure is acquired. The authors' data also suggested that procedural skill is acquired simultaneously, in which the SMA plays an important role. In contrast, the posterior part of the basal ganglia and the dentate nucleus of the cerebellum contribute to the long-term learning stage, in which the procedure is executed implicitly with a chain of anticipatory movements.

Based on their results and the results from other laboratories, the authors propose a hypothetical scheme in which a sequential procedure is learned independently by two parallel mechanisms in the cerebral cortex that use the visual and motor coordinates. Both of them are supported by the basal ganglia and the cerebellum: The basal ganglia provided them with reinforcement signals, and the cerebellum provided them with timing information. The proposed neural architecture would operate in an effective and flexible manner to acquire multiple sequential procedures.

Intelligence is based on the ability to learn a complex sequence of movements, as implicated in the usage of tools (Matsuzawa, 1996) and languages (Kuhl, 1994). How we learn such sequential procedures has been a long-standing objective of psychology and currently is a major topic in neuroscience. However, our understanding is far from complete. We hardly are able to pinpoint the brain structures that are critical for the sequential procedural learning. A consensus among neuroscientists is that the brain regions that are critical for declarative memory, including the hippocampus, are not critical for procedural learning or memory (Squire and Zola, 1996). Therefore, the procedural memory has been characterized by exclusion—that is, what is left out of the declara-

tive memory mechanisms. Interestingly, this is the very reason why many neuroscientists currently are interested in disclosing the mystery of procedural learning.

In this review, we first describe the current status of the research on procedural learning, then summarize our study on monkeys and humans, and finally propose a neural network model as an attempt to integrate results from our and other laboratories.¹

Brain regions that are implicated in procedural learning

As summarized in table 39.1, a number of brain regions have been shown to be involved in different types of learning. Interestingly, learning of sequential procedures currently is a major issue in studies using human subjects, but it rarely has been studied using animal subjects. Sequential procedures have been used in animal studies only after they have been learned to study the control mechanism of sequential movements (Tanji and Shima, 1994).

However, many of the human studies, especially imaging studies using positron-emission tomography (PET) or functional magnetic resonance imaging (fMRI), have focused on learning of sequential movements, such as the serial reaction time (SRT) task (Nissen and Bullemer, 1987). Common to the results of these studies was that several brain areas were active concurrently during learning, including the cerebral cortex, the basal ganglia, and the cerebellum. It has been proposed that there are different stages in learning to which different brain regions contribute (Karni et al., 1998; Petersen et al., 1998; Shadmehr and Brashers-Krug, 1997).

However, it still was unclear whether these brain regions actually contribute to the learning and how they interact with each other during learning. Crucial to answering this question was: (1) to identify the brain regions that were active with learning and (2) to manipulate the activity of each region to see whether learning and retention of memory were disrupted. Our strategy was to combine animal and human experiments

using the same task for learning of sequential procedures and examine how different brain regions contribute to the learning process. The results are summarized in the following section.

Strategy for searching the neural correlates of sequence learning

A sequential procedure is complex and therefore difficult to learn. This may be why few studies have been

done using animal subjects. Our 2×5 task was designed to overcome this difficulty (figure 39.1) (Hikosaka et al., 1995). A sequence (hyperset) in this task has a hierarchical structure such that the final goal (completion of hyperset) is reached by passing through successive subgoals (completion of set); a successive increase of partial reinforcement led to maximum reinforcement at the final goal. This reinforcement schedule apparently keeps the animals' motivation at a high level and allows them to acquire the procedure for a new sequence in a

Studies using animal and human subjects are shown separately. Studies on learning of simple reflexes are not listed. Studies from our laboratory are in *italics*. Abbreviations: prefrontal cortex (PF), ventral prefrontal cortex (vPF), parietal cortex (PA), cingulate cortex (Cing), S1 (primary somatosensory cortex), cerebellar cortex (Cbl-Ctx), cerebellar nuclei (Cbl-N), cerebellum in general (Cbl), basal ganglia (BG), striatum (Str), substantia nigra (SN). Hip (-) indicates that the hippocampal region was unrelated to learning. See Note 1 for other abbreviations.

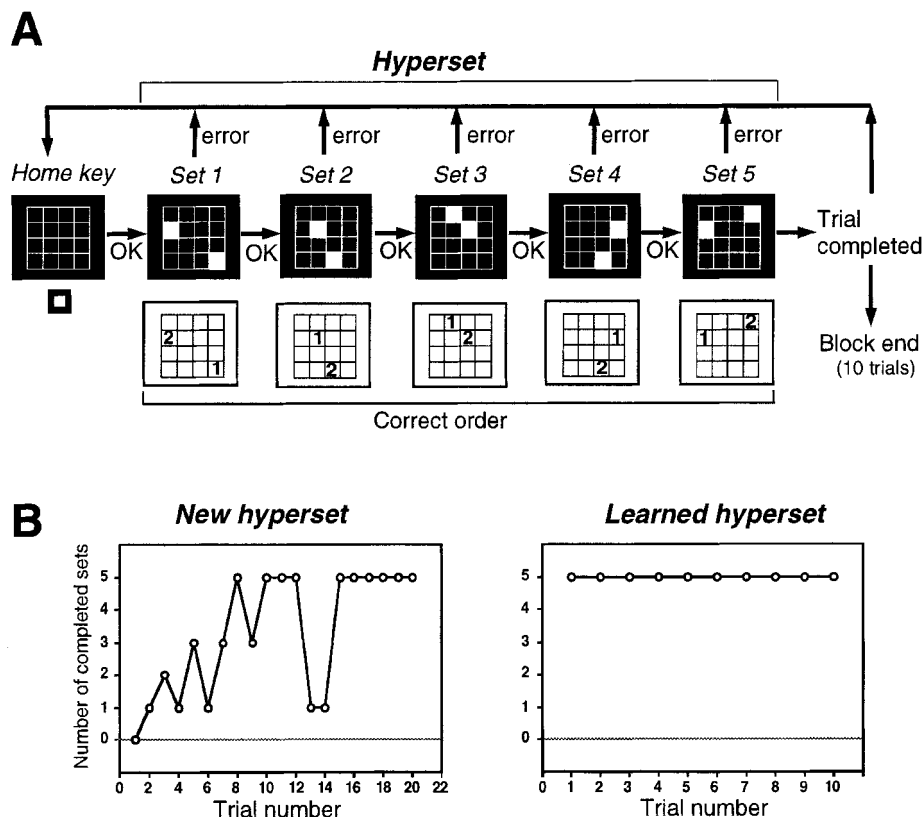

FIGURE 39.1 Procedure of 2×5 task. (A) In front of the monkey is a panel on which 16 LED buttons are arranged in a 4×4 matrix. Beneath the panel is another button called the “home key.” If the monkey presses the home key, 2 of the 16 LED buttons are illuminated simultaneously. The monkey has to press them in a correct (predetermined) order, which he has to find out by trial and error. This is called “set.” If successful, the LED buttons turn off sequentially and another pair of LEDs, a second set, is illuminated that the monkey has to press again in a correct order. A total of five sets is presented in a fixed order for completion of a trial, which we call “hyperset.” If the monkey presses a wrong button, the trial is aborted, and the mon-

short period (usually less than 4 min). Furthermore, the 2×5 task allows us to generate new sequences, practically as many as possible.

Our experimental strategy was composed of three lines of experimental procedures: (1) initial training of learning procedures, (2) behavioral experiments, and (3) physiological experiments.

First, we had the monkeys learn a set of sequences repeatedly until they could perform the sequences highly skillfully, presumably based on long-term memories or programs for the sequences. We then would be ready to search for the neural mechanisms that are involved in the memory storage or retrieval processes. Conversely, by having the monkeys learn new sequences repeatedly, we would be ready to search for the neural mechanisms that are involved in learning of new procedures.

key has to start again from the home key as a new trial. Each hyperset was presented repeatedly in a block until 10 to 20 successful trials were performed. A different hyperset then was used for the next block. (B) An example of a block of practice trials using a new hyperset (left) and a learned hyperset (right). The numbers of completed sets (ordinate) are shown for consecutive trials (abscissa). In the learned hyperset, the monkey completed the block (10 successful trials) with no error. In the new hyperset, the same monkey made errors initially at the first or second set, but the number of completed sets increased gradually.

The second procedure, behavioral experiments, was performed to correlate the process of learning using the 2×5 task with a large number of human behavioral studies (table 39.1). We showed that the monkeys learned individual sequences in the same way as human subjects do, for example, following the “law of practice” (Newell and Rosenbloom, 1981). In addition, we found interesting observations that would be correlated with underlying neural mechanisms (summarized in table 39.2 and described in detail in the following section).

Finally, we attempted to find the neural correlates of sequence learning using two approaches: activation study (single-unit recording in monkeys and fMRI in humans) and inactivation study (reversible blockade by muscimol injection). The activation and inactivation studies are complementary for the following reasons. The activation study could produce false-positive errors:

TABLE 39.2
Learning stages in 2 × 5 task

Stage	Early	Intermediate	Late
Specific to hand?	No		Yes
Specific to order?	No		Yes
Quick?	No		Yes
Anticipatory movements?	No		Yes
Forget on next day?	Yes		No
Forget after 6 months?	Yes		No
Classification	Declarative Explicit Knowledge		Procedural Implicit Skill
Brain areas			
Cerebral cortex	Pre-SMA DLPFC	SMA IPS Precuneus	
Basal ganglia	Anterior striatum		Putamen
Cerebellum			Dentate nucleus

Note that the distinction between the early and late learning stages may not be so clear as indicated here (e.g., performance in the late stage is not absolutely specific to the hand). The SMA, IPS, and precuneus are classified as an intermediate group for the following reasons. The SMA, compared with the pre-SMA, contributes to the motor aspect of learning. The IPS and precuneus become active in the later phase of short-term learning.

Abbreviations: Supplementary motor area (SMA), dorsolateral prefrontal cortex (DLPFC), intraparietal sulcus (IPS).

even if a particular set of neurons of brain regions is activated with learning, it may not be actually necessary for learning. Conversely, the inactivation study could produce false-negative errors: even if inactivation of a particular brain region does not disturb learning processes, other intact brain regions could compensate for the function subserved by the inactivated region.

Multiple stages in visuomotor sequence learning

By training monkeys with the 2 × 5 task, we found that sequence learning is composed of at least three stages (Hikosaka et al., 1995): (1) short-term sequence-selective stage, (2) long-term sequence-selective stage, and (3) long-term sequence-unselective stage.

SHORT-TERM SEQUENCE-SELECTIVE STAGE On encountering a completely new sequence (2 × 5), our monkeys, after trial-and-error processes, learned to perform the sequence correctly within a few minutes. Although they knew what to do by then, their performance was far from skillful and was slow. On the next day, the monkeys again made some errors for the same sequence (although the number of errors became fewer).

LONG-TERM SEQUENCE-SELECTIVE STAGE After practice of the same sequence for 30 days or more, the monkeys seldom made errors, and the performance became very skillful and fast, like a professional typist. A similar

improvement of performance occurred for each new sequence. In this way, the monkeys eventually acquired a set of learned sequences for which they were very skillful. This ability was retained for a long time without practice (e.g., 6 months) (Hikosaka, Miyachi, et al., 1996).

LONG-TERM SEQUENCE-UNSELECTIVE STAGE With a long-term experience of the 2 × 5 task (e.g., more than 1 year), the monkeys mastered a new sequence with progressively fewer errors. It appeared that they acquired better strategies to learn new sequences.

Emergence of anticipatory movements with long-term practice

There were distinct differences between the short-term learning and the long-term learning (table 39.2) because the performance was much faster in the long-term stage. This was not because the hand movements per se became faster. In fact, the movement time (time between the first and second button presses when the movement was guided fully by visual stimuli) was not different between new and learned sequences or was even shorter for new sequences. A major factor that made the performance faster was the shortening of the button press reaction time (time from stimulus onset to the first button press in each set) (Miyashita et al., 1996). In the short-term stage of learning, the monkeys initiated a saccadic eye movement to one of the two LED buttons after they

were illuminated (react-mode). In contrast, in the long-term stage of learning, the monkeys initiated a saccade and hand movement to the correct one of the two LED buttons before they turned on; when the buttons turned on, the gaze already was directed at the correct button, and the hand was positioned close to it (anticipatory mode). Thus, the reaction time was much shortened in the long-term stage compared with the short-term stage, even though the speed of movements was unchanged.

Transition from knowledge to skill with long-term practice

There were additional observations that distinguished the short-term and long-term stages of learning. We had the monkeys use either the right or left hand for a given sequence throughout the learning period. As a result, each monkey had a repertoire of learned sequences, half of which were learned with the right hand and the other half with the left hand. When the monkeys were asked to use the hand that had not been used for long-term practice for a given sequence, their performance became very poor in terms of the number of errors and the performance time, although it was better than the performance for new sequences (Rand, Hikosaka, et al., 1998). However, this was not true for a newly learned sequence. We compared two learning schedules in which a new sequence is learned for two blocks in two consecutive days: (1) using the same hand and (2) using different hands. The performance improved in both cases, although the improvement was somewhat greater in the case of the same hand (Rand et al., unpublished observation). These results suggest that, in the short-term stage of learning, the memory for a visuomotor sequence is accessible to both the trained hand and the untrained hand, implying that the monkeys had explicit knowledge for the sequence, presumably in the visual coordinates. After long-term practice, however, the memory would become largely inaccessible to the untrained hand, implying that the monkeys now relied on implicit skill for performing the sequence.

Human psychological studies have suggested that procedural skill learning involves a declarative-to-procedural transition of learning stages (Fitts, 1964; Anderson, 1982). However, there has been no appropriate experiment using animal subjects to investigate neural mechanisms underlying such a transition of learning stages. Recent human imaging studies have indicated that the pattern of brain activation changes with practice (table 39.1). Some of them may be related to the declarative-to-procedural transition, but there have been few attempts to correlate the brain activation to the transition of learning stages (Sakai et al., 1998). In this sense, our 2×5 task provides an ideal environment to address this issue.

Sequence rather than individual elements is learned

Another interesting observation was on the difference in the nature of memories between the short-term and long-term stages. As already described, each sequence (hyper-set) was composed of five sets in which a correct order of button presses was predetermined. After the monkeys acquired a number of learned sequences with long-term practice, we reversed the order of sets while the correct order of button presses remained the same for each sets. Our experiments showed that the performance for the reversed sequences was very poor, as if the monkeys were performing completely new sequences (Rand, Hikosaka, et al., 1998). The result suggests that the monkeys acquired the memories for the whole sequences, rather than the memories for individual elements (sets) separately.

However, this was not necessarily true in the short-term stage of learning. When the monkeys were required to perform the reversed sequence after learning of the original sequence only once, one of the two monkeys tested showed improvement of performance in the same way as when they performed the original sequence again (Rand et al., unpublished observation).

These results suggest that memories are created first for individual elements in a sequence, which then are compiled into a composite memory for the whole sequence after long-term practice. In other words, the monkeys remembered individual elements initially, but not after long-term practice. This is consistent with the aforementioned idea that practice is associated with an explicit-to-implicit transition of procedural memory.

Physiological studies already have disclosed some hints on this issue. That is, neurons that change their activity with particular transitions or combinations of movement sequences, rather than movements per se, have been found in the supplementary motor area (Mushiake, Inase, and Tanji, 1991), caudate nucleus (Kermadi and Joseph, 1995), globus pallidus (Mushiake and Strick, 1996), and dentate nucleus (Mushiake and Strick, 1993).

We wanted to know how such sequential transitions are implemented as neural signals with practice and decided to examine different brain areas using the same 2×5 task, as shown in the following section.

The presupplementary motor area and the supplementary motor area contribute to learning of new sequences, but in different ways

BACKGROUND The medial part of the frontal cortex includes at least two areas that are related intimately to voluntary movements: the supplementary motor area (SMA) and the pre-SMA (Tanji, 1994). There is evidence that the SMA is related to the *control* of sequential

movements (Tanji and Shima, 1994), bimanual coordination (Brinkman, 1984), and internally guided movements (Halsband, Matsuzaka, and Tanji, 1994).

We hypothesized, therefore, that the medial frontal cortex also plays an important role in *learning* of sequential movements. Our study using the 2 × 5 task indicated that the pre-SMA, rather than SMA, contributes to the initial learning of visuomotor sequences (Nakamura, Sakai, and Hikosaka, 1998, 1999). The results were obtained in three lines of experiments (table 39.3): (1) single-unit recording, (2) reversible inactivation (both using monkeys), and (3) fMRI using human subjects.

2 × 5 TASK: SINGLE-UNIT RECORDING We recorded the activity of single neurons in the medial frontal cortex while the monkeys were performing three to five new sequences and three to five learned sequences (Nakamura, Sakai, and Hikosaka, 1998). We found that many neurons became active preferentially while the monkeys were trying to learn new sequences. Such “new-prefering” neurons were more prevalent in the pre-SMA than in the SMA. A typical pre-SMA neuron would show phasic activity before the first button press for each set if the sequence was new, whereas the same neuron would show almost no activity when the sequence had been learned. The activation for new sequences was unrelated to the side of the hand performing the task; it occurred when either the contralateral or ipsilateral hand was used. There are some neurons that were active preferentially for learned sequences, but their number is smaller and tended to be found in the SMA. These results suggest that the medial frontal cortex, especially the pre-SMA, is related to new learning, rather than long-term memory storage or retrieval.

TABLE 39.3

Summary of 2 × 5 experiments on medial frontal cortex

Brain Region	pre-SMA	SMA
Single-cell activity	New > learned	New = learned
No. of errors		
New	Increase++	Increase ±
Learned	No change	No change
Button-press RT		
New	Increase+	Increase++
Learned	Increase+	Increase+
Anticipatory saccade		
Learned	No change	No change
Hand preference	Bilateral	Contra/bilateral

Hand preference is not absolute; e.g., many neurons in the SMA were preferentially active for the contralateral hand.

Abbreviations: supplementary motor area (SMA), response time (RT).

2 × 5 TASK: REVERSIBLE INACTIVATION To test this hypothesis, we locally and reversibly inactivated different portions of the pre-SMA and the SMA by injecting a small amount of muscimol unilaterally (Nakamura, Sakai, and Hikosaka, 1999). After a muscimol injection, we had the monkeys perform new and learned sequences. We found that the number of errors (sequence errors) increased for new sequences, but not for learned sequences. This effect was stronger after pre-SMA injections than SMA injections, as expected from the results of single-unit recording. Furthermore, the effect was present when either the contralateral or ipsilateral hand was used, particularly after the pre-SMA injections, again being consistent with the recording data.

Conversely, movement parameters, such as button press reaction time (BP-RT), were affected more clearly by SMA injections. The BP-RT, which is the time from the onset of two target stimuli to the first button press, was much shorter for learned sequences because the hand moved in an anticipatory manner toward the location of the target before it was illuminated (see aforementioned discussion). This parameter thus reflected how anticipatory the performance was, rather than how fast the individual movements were. The BP-RT for new sequences increased after muscimol injections in the SMA more clearly than injections in the pre-SMA. However, anticipatory saccades were not affected by inactivation of either the SMA or the pre-SMA.

2 × 5 TASK: INTERPRETATION These results, taken together, suggest that both the pre-SMA and the SMA contribute to learning of new sequences, but in different ways. The pre-SMA contributes to the acquisition of correct orders of button presses, whereas the SMA contributes to the acquisition of quicker performance with anticipatory movements. In addition, it was found that more than half of SMA neurons were active preferentially when the contralateral hand was used, whereas most pre-SMA neurons showed no preference for either the contra- or ipsilateral hand.

The difference between the pre-SMA and the SMA led us to propose the following hypothesis: The pre-SMA works to acquire explicit knowledge, whereas the SMA works to acquire implicit skill. Knowledge would be evaluated by the number of errors (in accordance with pre-SMA inactivation), whereas skill would be evaluated by the performance speed (in accordance with SMA inactivation). Knowledge should be unrelated to the performing hand (in accordance with pre-SMA activity), whereas skill may be specific to the hand (in accordance with SMA activity).

2 × 10 TASK: HUMAN FUNCTIONAL MAGNETIC RESONANCE IMAGING (MEDIAL FRONTAL CORTEX) The aforementioned findings in animal studies are supplemented by the fMRI experiments on human subjects (Hikosaka et al., 1996b). We used basically the same task for human subjects except that the sequence was 2 × 10 or 3 × 10 and that the rate of button presses was made constant. For comparison, we used a task in which the subjects were allowed to press buttons in any order. The learning (i.e., learn—any order) was associated with consistent activation of a region in the medial frontal cortex that was slightly anterior to the anterior commissure. We designated this region as a human homologue of the pre-SMA, in accordance with the suggestion proposed by Picard and Strick (1996). The human pre-SMA was not activated with sequential button presses if no learning was involved (any order—rest). Conversely, the SMA, a region posterior to the anterior commissure, was activated with such sensory-motor processes (any order—rest) but not with learning.

Frontal-to-parietal transition of learning-related activation

BACKGROUND As described in table 39.1, other human imaging studies have shown that multiple brain regions were activated with sequence learning. It therefore is unlikely that only the pre-SMA is related to learning in the 2 × 10 task. We therefore extended our survey of fMRI by examining the activity of the whole frontal, parietal, and occipital areas.

2 × 10 TASK: HUMAN FUNCTIONAL MAGNETIC RESONANCE IMAGING We found that at least four cortical regions were active with learning (Sakai et al., 1998): (1) medial frontal cortex (pre-SMA), (2) lateral frontal cortex (dorsolateral prefrontal cortex), (3) medial parietal cortex (precuneus), and (4) lateral parietal cortex (intraparietal sulcus region) (figure 39.2). Interestingly, there was a global transition of activity from the two frontal regions to the two parietal regions, although the subjects were learning a single visuomotor sequence. Thus, the lateral frontal cortex was active in the early phase, the pre-SMA in the early and intermediate phases, the precuneus in the intermediate phase, and the lateral parietal cortex in the intermediate and advanced stages.

2 × 10 TASK: INTERPRETATION The frontal activation corresponded to the initial learning phase, during which the performance time increased nearly linearly with the number of targets (if the subjects were asked to perform as quickly as possible), suggesting that the information was processed in a sequential manner—a

characteristic feature of attentive processes (Schneider and Shiffrin, 1977). Conversely, the parietal activation corresponded to the intermediate or late phase of learning, during which the performance time decreased, suggesting that the information was processed, at least partly, in a parallel manner—a characteristic feature of automatic processes (Fendrich, Healy, and Bourne, 1991).

2 × 10 TASK: FURTHER STUDIES To investigate the nature of pre-SMA activation, we modified the 2 × 10 task in two ways: (1) a 2 × 10 color sequence task and (2) a 2 × 6 position mapping task. In the 2 × 10 color task, the targets appeared with one of four colors, and the subjects had to press buttons in the correct orders based on their colors, not their positions. The pre-SMA still was active with learning. In the 2 × 6 mapping task, six pairs of targets (set) with different configurations appeared in a random order so that the subjects had to remember the correct order of button presses depending on the target configuration. The pre-SMA again was active, and this time remained active even after acquisition of button press orders. In short, the pre-SMA becomes active when the response is determined by the current sensory inputs, rather than by the predetermined procedure.

Anterior/posterior functional differentiation of the basal ganglia

BACKGROUND The basal ganglia have been implicated in reinforcement learning (Robbins and Everitt, 1996; Houk, Adams, and Barto, 1995) and implicit learning (Jackson et al., 1995; Knowlton, Mangels, and Squire, 1996). The role of the basal ganglia in learning also is supported by adaptable changes in neuronal activity in the basal ganglia (Graybiel et al., 1994; Schultz, Apicella, and Ljungberg, 1993; Kawagoe, Takikawa, and Hikosaka, 1998). Neurons in the striatum show activity that anticipates upcoming sensory and motor events (Hikosaka, Sakamoto, and Usui, 1989; Schultz et al., 1992) and show sequence-dependent activation (Kermadi et al., 1993). These results suggest that the basal ganglia are related to learning and memory of sequential procedures.

2 × 5 TASK: REVERSIBLE INACTIVATION We inactivated different portions of the caudate and putamen by injecting muscimol, usually bilaterally (Miyachi et al., 1997). We classified injection sites into three classes: (1) anterior striatum (head of the caudate and the anterior part of the putamen), (2) mid-posterior putamen, and (3) mid-posterior caudate (figure 39.3; table 39.4). The inactivation of the anterior striatum led to increases in the

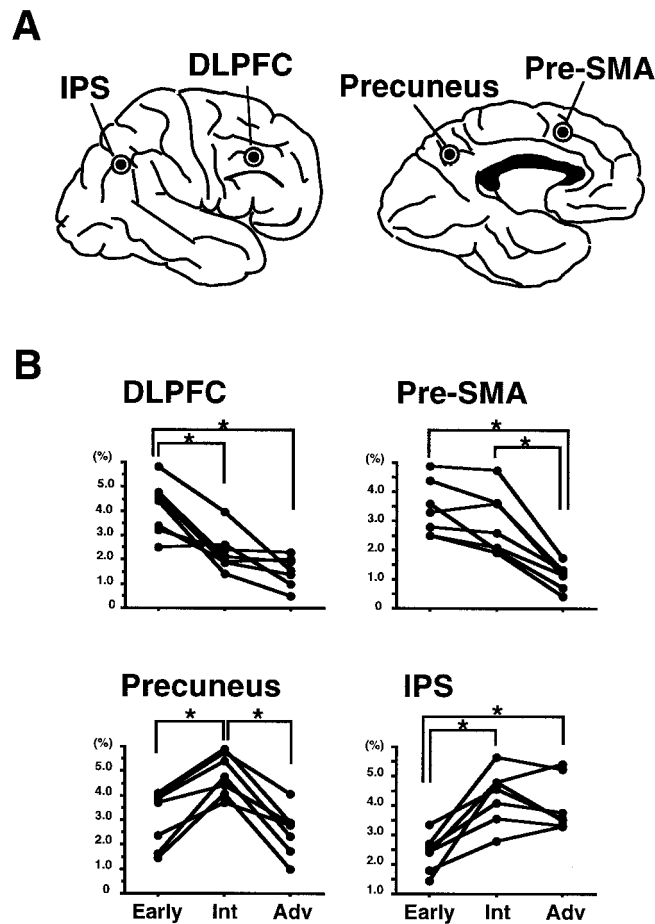

FIGURE 39.2 Transition of learning-related brain activation. Correlation of cortical activation with learning stages. (A) Four cortical areas related to learning of visuomotor sequences: dorsolateral prefrontal cortex (DLPFC), presupplementary motor area (pre-SMA), precuneus, and intraparietal sulcus (IPS). (B) For each cortical area, data obtained from six subjects are

shown for the three learning stages: early (left), intermediate (center), and advanced (right) stages. Paired comparisons were made between the learning stages using Wilcoxon's signed rank test; significant differences ($P < .05$) are indicated by asterisks.

number of sequence errors highly significantly for new sequences and weakly significantly for learned sequences. The inactivation of the mid-posterior putamen led to an increase in the number of errors significantly for learned sequences but not new sequences. The inactivation of the mid-posterior caudate produced effects that were inconsistent and variable.

These results suggest that the anterior striatum is related mainly to acquisition of new sequences, whereas the mid-posterior striatum (putamen) is related to storage or retrieval of long-term memories. The aforementioned suggestion was confirmed by single-unit recordings: neurons in the anterior striatum tended to be more active for new sequences whereas neurons in the mid-posterior putamen tended to be more active for learned sequences.

2 × 5 TASK: INTERPRETATION The results suggest that the anterior and posterior portions of the basal ganglia

contribute to learning of visuomotor sequences in different ways. What are the relationships between the basal ganglia and the cerebral cortex?

The cerebral cortex and the basal ganglia connect with each other, forming loops of neural circuits, each of which may have a unique function (Alexander and Crutcher, 1990). The anterior-posterior functional differentiation of the basal ganglia suggested by our study may be related to such multiple corticobasal ganglia networks. Thus, the anterior part of the striatum together with the association cortex (especially the dorsolateral prefrontal cortex) form a "cognitive" circuit. However, the mid-posterior portion of the putamen together with the sensory-motor cortex form a "motor" circuit.

Our results are consistent with this view because the anterior striatum (in monkeys) and the dorsolateral prefrontal cortex (in humans) are active in the early stage of

FIGURE 39.3 Sites of muscimol injection in the striatum at three anteroposterior levels (from top to bottom): 6 mm anterior, 2 mm anterior, and 2 mm posterior to the anterior commissure (AC). These injection sites were classified into three groups: anterior striatum (crosses); mid-posterior putamen (filled circles); mid-posterior caudate (open circles). Results are summarized in table 39.4.

learning and that the inactivation of the anterior striatum disrupted new learning. Conversely, it is tempting to presume that the mid-posterior part of the putamen together with some part of the sensory-motor cortex work for storage and retrieval of sequence memories. The SMA is a candidate for this role (Schell and Strick, 1984), but our data suggested that it also contributes to new learning (Nakamura, Sakai, and Hikosaka, 1999). Another possibility is that the presumed role of the mid-posterior putamen in memory storage and retrieval is related to its connection with the primary motor cortex (Künzle, 1975; Hoover and Strick, 1993).

Cerebellar dentate nucleus contributes to long-term memory for procedural skill

BACKGROUND It is well known that the ability to adjust parameters of reflexes and simple movements is lost without the cerebellum (Thach, Goodkin, and Keathing, 1992). One therefore might assume that the cerebellum

also plays an important role in learning of more complex actions, such as learning of sequential procedures. Although there have been few animal studies focussed on sequence learning, many human imaging studies have shown that the cerebellum is activated during different types of motor and nonmotor learning, including sequence learning (table 39.1). However, in these studies, the precise function and locus for sequence learning were unknown.

2 × 5 TASK: REVERSIBLE INACTIVATION We inactivated different portions of the cerebellar nuclei (dentate, interpositus, and fastigial nuclei) by injecting muscimol unilaterally (Lu, Hikosaka, and Miyachi, 1998) (figure 39.4; table 39.5). When the dorsal or central part of the dentate nucleus was inactivated, the number of errors increased significantly for learned sequences but not for new sequences; inactivation of the lateral or ventral portion of the dentate nucleus, interpositus nucleus, or fastigial nucleus produced no effect on learning or memory. Further, the effect was present only when the hand ipsilateral to the injection was used.

Conversely, slowing of movements occurred after any of these inactivations, but again for the ipsilateral hand. This result suggests that the deficits after the inactivation of the dorsal-central portions of the dentate nucleus were not contingent on the movement deficits but reflect the memory deficits.

2 × 5 TASK: INTERPRETATION The results suggest that the dorsal and central portions of the dentate nucleus are selectively related to the storage or retrieval of long-term procedural memories for the ipsilateral hand. The unilateral nature of the cerebellar functions is consistent with the former behavioral study showing poor transfer of long-term memory: The monkeys had difficulty in performing learned sequences when they were asked to use the hand that was not used for practice (Rand, Hikosaka, et al., 1998). It also suggests that the cerebellum contributes to implicit skill rather than explicit knowledge. This contrasted with the presumed role of the pre-SMA and dorsolateral prefrontal cortex.

FIGURE 39.4 Effects of muscimol injection in the cerebellar nuclei. The cerebellar nuclei on one side (top) are shown enlarged below. The number of errors for learned, but not new, sequences increased after the injections in the dorsomedial, dorsolateral, and central parts of the dentate nucleus (DN). The movement time increased after all injections including the interpositus nucleus (IPN) and fastigial nucleus (FN), except for the injection above the dentate nucleus. See also table 39.5.

The “memory” area of the dentate nucleus, especially the dorsal part, is known to project to the M1 through the thalamus (Middleton and Strick, 1996). It thus is tempting to hypothesize that the cerebello-cerebral network underlies the formation of motor skill. In fact, recent studies have indicated that practice-dependent changes occur in the M1 in animals (Nudo et al., 1996; Asanuma and Pavlides, 1997) and humans (Karni et al., 1995; Classen et al., 1998).

However, human and animal studies have shown that the cerebellum tends to be active in the early stage of learning (table 39.1). We interpret the seeming discrepancy between our results and the results of other studies as follows. The cerebellum may start working from the beginning of learning, but its role is not yet critical because other areas, including the pre-SMA and the anterior striatum, work in parallel to acquire knowledge for correct performance. After long-term practice, however, the performance becomes more dependent on the cerebellar mechanism, which enables quick and skillful

movements but is specific to the hand used for the practice. It is unknown, if this is the case, whether the same portion of the dentate nucleus is involved in the early learning process.

Other brain areas also may contribute to sequence learning

Our fMRI study (Sakai et al., 1998) raised the possibility that the medial and lateral parts of the parietal cortex is involved in learning visuomotor sequences. Although the parietal areas were activated after the frontal areas, their activation largely disappeared after an extensive practice (Sakai et al., 1998). This might indicate that the parietal cortex is related to learning in its intermediate stage.

Findings on the medial part of the parietal cortex (precuneus) in human imaging studies might be relevant to our results. Thus, mental navigation of familiar routes was associated with distinct activation of the precuneus (Ghaem et al., 1997; Maguire, Frackowiak, and Firth, 1997). Crucial in navigation is the information on visuomotor sequences, as in our 2×10 task.

Other brain regions to be studied include the premotor cortex, cingulate cortex, hippocampal region, and limbic system. There has been no attempt in animal studies to study these areas in relation to learning of sequential procedures.

Parallel networks for procedural learning—A hypothesis

CONCEPTUAL SCHEME Based on the results of our studies and other related studies, we propose a hypothesis on the neural mechanism for learning of visuomotor sequences. A key feature of our hypothesis, shown in figure 39.5A (see also color plate 24), is that there are separate systems in the brain that contribute to different aspects of visuomotor sequence learning (Nakahara, 1997; Nakahara et al., 1997). Here we postulate “event sequence system” and “action sequence system,” which work independently. They use different coordinate systems: the visual and motor coordinates, respectively. There are two ways in which these learning systems communicate with each other: through a “coordinator” and a “translator.” The coordinator determines to allow or disallow the opponent system to work, whereas the translator converts information from one coordinate to the other.

We further hypothesize that there are two systems that support the parallel learning systems: (1) the reinforcement learning system and (2) the motor sequence system. The reinforcement system (assigned to the basal

TABLE 39.5

ganglia) determines whether a sequence of events or actions is to be learned; this is based on whether the final outcome of the action sequence is beneficial (or rewarding) for the animal. The motor sequence system (assigned to the cerebellum), by interacting with the event and action sequence systems, works to refine the movements constituting each action.

NETWORK MODEL Let us elaborate on the hypothesis by relating these functional modules to actual brain areas, as shown in figure 39.5B. We try to reach an agreement based on three sources of information: (1) our experimental findings, (2) experimental findings from other laboratories, and (3) known anatomic connections. There may, of course, be other ways to do so, and the scheme in figure 39.5B is subject to change in the course of future studies.

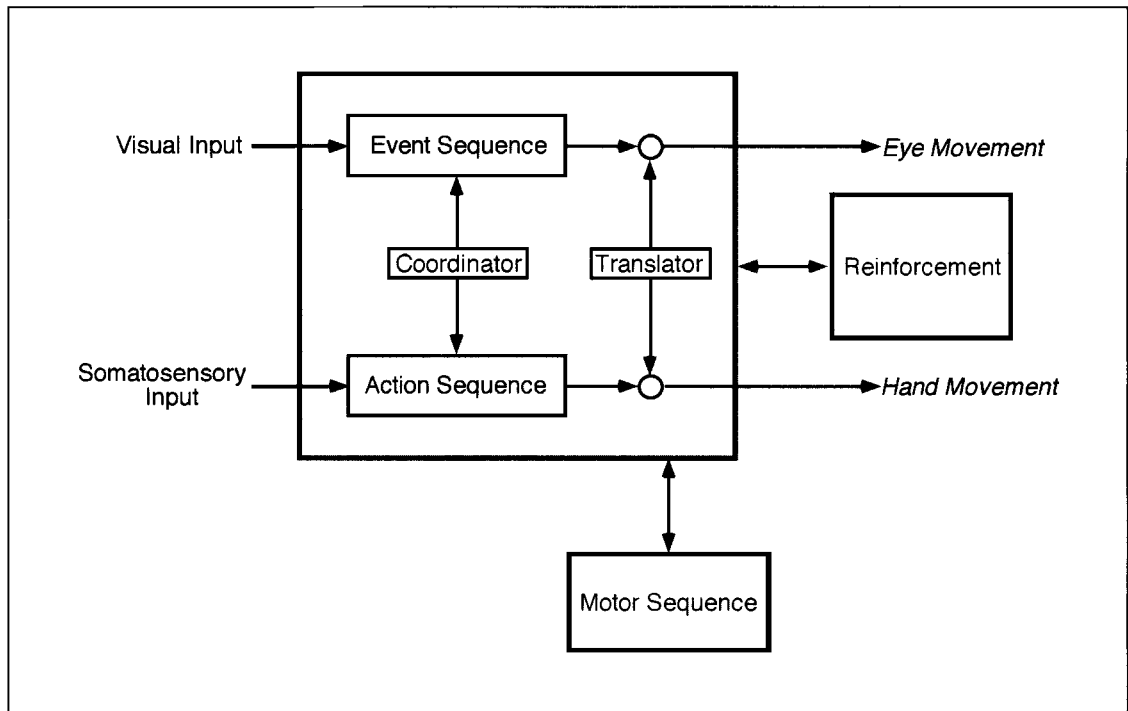

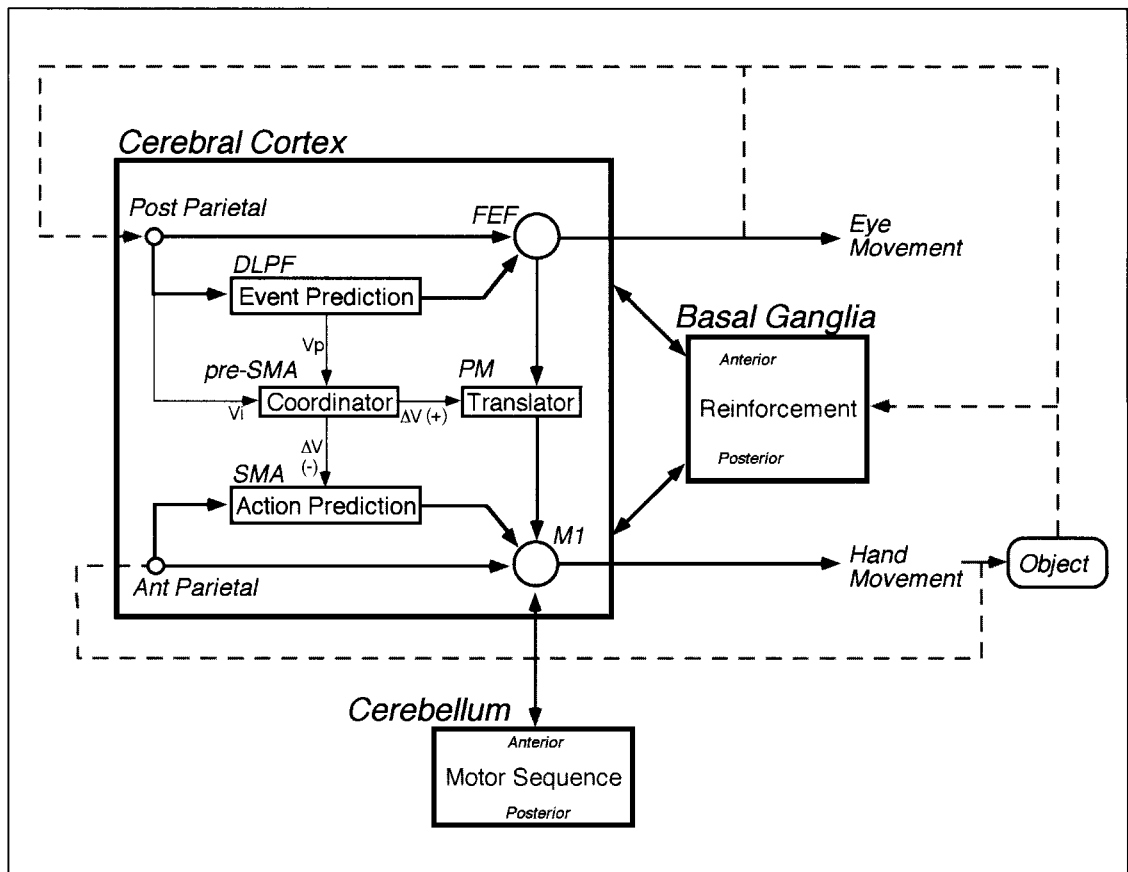

We assign the event and action sequence systems, respectively, to the dorsolateral prefrontal cortex (DLPF)² and the SMA.³ We have added two pathways that bypass these systems; they would work when no learning is involved: (1) the pathway from the posterior parietal cortex to the frontal eye field for visually guided saccadic eye movements (Schall et al., 1995) and (2) the pathway from the anterior parietal cortex to the motor cortex for hand movements guided by somatosensory means (Strick and Kim, 1978). In figure 39.5A, the coordinator and translator are indicated to be bidirectional, but we consider a unidirectional case in figure 39.5B, from the event sequence system to the action sequence system.

The coordinator (assigned to the pre-SMA) compares the current visual input (Vi) and the predicted visual input (Vp) and, if they do not match (mismatch indicated by ΔV), suppresses the learning function of the action sequence system and at the same time facilitates the translator. The predicted input is provided by the event sequence system.⁴ The mismatch between the current and predicted inputs (ΔV) would occur on

two occasions: (1) when the animal starts to learn a new sequence (Nakamura, Sakai, and Hikosaka, 1998) and (2) when the sequence is changed (Shima et al., 1996; Matsuzaka and Tanji, 1996). In this case, the visual input is used directly to guide eye movements through the frontal eye field (FEF) and indirectly to guide hand movements through the translator (assigned to the premotor area [PM]⁵), while the event sequence system learns the visual sequence. The translator is needed because the retinotopic information must be translated into the somatotopic information, a process frequently called “inverse kinematics” (Kawato, Furukawa, and Suzuki, 1987).

As the event sequence system learns the visual sequence, its output (predicted visual input) matches the current visual input, so that the coordinator (pre-SMA) becomes inactive⁶ and therefore the action sequence system starts to learn the sequence.⁷ At this stage, however, the learning of motor sequences still is guided by the visually guided mechanism, which involves the posterior parietal cortex, the FEF, and the PM.⁸ By repeating this procedure, the motor sequence system implements the sequence in the motor

FIGURE 39.5 A model for learning of sequential procedures based on our data and the data from other laboratories. (A) Conceptual scheme that postulates two parallel learning systems, one using the visual coordinates (event sequence system) and the other using the motor coordinates (action sequence system). They communicate with each other by means of a coordinator and a translator. We further postulate two subsystems. The reinforcement system acts to decide which sequences are to be learned. The motor sequence system acts to refine individual movements constituting the action sequence. (B) An attempt to correlate the conceptual scheme with actual brain regions. Visual information during the performance of sequence procedures is fed back to the event sequence system (event predictor, assigned to the DLPF) by means of the inferior parietal cortex, whereas motor (or somatosensory) information is fed back to the action sequence system (action predictor, SMA) by means of the superior parietal cortex.

A**B**

coordinates and finally dominates over the visually guided system.

The key role of the reinforcement system (assigned to the basal ganglia) is to determine whether current or preceding actions are beneficial for the animal. The dopaminergic system in the basal ganglia would carry such reinforcement signals to the striatum to enhance or depress the corticostriatal synapses (Schultz et al., 1992). The evaluated signals would then be fed back to the corresponding cortical regions to modulate the cortical learning processes (Hikosaka, 1994). The ability of the basal ganglia system to predict upcoming reward (Houk, Adams, and Barto, 1995) is very useful in learning of behavioral sequences. Different parts of the basal ganglia would guide different parts of the cerebral cortex. For example, the anterior portion of the striatum is connected with the cortical areas related to the event sequence system, whereas the posterior striatum (putamen) is connected with the cortical areas related to the action sequence system (Parent, 1990), consistent with the results of our inactivation experiments (Miyachi et al., 1997).

The motor sequence system (assigned to the cerebellum) contributes to refinement of individual movements constituting an action, which is the basis of motor skill. Particularly important in such motor skill would be the control and learning of timing.⁹ We postulate that the anterior part of the cerebellum learns to implement time sequences, whereas the posterior part detects the difference between the predicted timing and the actual timing¹⁰—an algorithm similar to that for the DLPF and pre-SMA. After long-term practice, the anterior cerebellum acquires a fixed timing sequence, the predicted timing matches the actual timing, and therefore the posterior cerebellum becomes inactive, and consequently the anterior cerebellum sends the predicted outputs to the M1 (Middleton and Strick, 1994). The performance at this stage is very skillful and stereotyped. It requires little activation of the visual sequence system and therefore is carried out without conscious control. The finely tuned timing information derived from the anterior cerebellum also would be critical in coordinating sequential transitions of different sensory-motor systems (Thach, Goodkin, and Keating, 1992). The anterior cerebellum would control exclusively one side of the hand (i.e., ipsilateral side), as Lu and associates (1998) demonstrated; otherwise, the animal would not be able to acquire skill for each hand.

OPPOSITE HAND EXPERIMENT Note that the action or motor sequence system is largely specific to the side of the performing hand, whereas the event sequence system is not. After long-term practice using one hand, the

performance is largely dependent on the outputs of the action and motor sequence systems. If the animal then is asked to use the opposite hand, the performance would be very poor because the action or motor sequence system for this hand has little access to the information on the learned sequence. This actually was demonstrated by Rand, Hikosaka, and associates (1998).

RELATION TO INACTIVATION EXPERIMENTS

Pre-SMA At the beginning of learning, the performance typically should be dependent on the event sequence system, which deals with visual and working memory information. The inactivation of the pre-SMA would have two effects. First, because the action sequence system is not suppressed in the early stage of learning, it acquires sequence information, whether it is correct or not. Such erratic motor signals would distract the correct performance. Second, because the translator (PM) does not receive excitatory inputs from the pre-SMA, visual sequence information would not be converted appropriately to motor information. These two effects, taken together, hinder the initial stage of sequence learning. In contrast, the performance after long-term practice is largely dependent on the action and motor sequence systems so that it hardly would be affected by the inactivation of the pre-SMA. This is exactly what Nakamura, Sakai, and Hikosaka (1999) demonstrated.

Striatum The anterior and posterior parts of the basal ganglia would provide the event and action sequence systems, respectively, with reinforcement signals. The inactivation of the anterior striatum would disrupt learning of event sequences, which is dominant in the early stage of sequence learning; the inactivation of the posterior striatum would disrupt learning of action sequences, which is dominant in the late stage. The results of Miyachi and associates (1997) correspond to this prediction.

Dentate nucleus of the cerebellum The dorsal part of the dentate nucleus is connected with the M1 (Middleton and Strick, 1994) to support the skillful and implicit performance. Inactivation of this region thus would affect the performance only after extensive practice and only when the ipsilateral hand is used, as demonstrated by Lu and associates (1998).

The inactivation of the posterior cerebellum and the ventral or lateral portion of the dentate nucleus would affect learning when it still is dependent on the visual sequence. We did not see such effects, perhaps because we did not inactivate the dentate nucleus bilaterally.

Conclusions

Based on behavioral experiments on trained monkeys, we have shown that learning of sequential procedures occurs in at least two stages: (1) a short-term stage (within a session), in which the subject correctly but slowly performs the sequence by reacting to individual visual stimuli (implying an explicit process); and (2) a long-term stage (across days), in which the sequence is performed quickly with a chain of anticipatory movements (implying an implicit process). Subsequent physiological experiments on trained monkeys and human subjects have revealed neural correlates of the transition of the learning stage because multiple brain regions contribute to the learning in different ways and with different time courses. The frontal cortex (pre-SMA and DLPF), together with the anterior part of the basal ganglia, contributes to the initiation of short-term learning, which is guided by visual information. The SMA, another part of the frontal cortex, also contributes to the short-term stage of learning, but more so for improvement of motor performance. The long-term learning stage is supported by the regions including the posterior part of the basal ganglia and the dentate nucleus of the cerebellum. The contribution of the cerebellum is limited to the hand used for practice, suggesting an implicit process (in agreement with the behavioral data).

However, our experiments showed that the learning was disrupted only partially by inactivation of one of these areas, suggesting that multiple regions subserve the learning concurrently. This led us to propose a model for learning of sequential procedures. A key feature of this model is that the information on a sequential procedure is acquired in parallel by two learning systems, one coding the sequence in the visual coordinates (event sequence system, assigned to DLPF) and the other coding the sequence in the motor coordinates (action sequence system, SMA). These systems communicate with each other via a coordinator (pre-SMA) and a translator (PM). In the course of learning, the coordinator acts to shift the weight of contribution from the event sequence system to the action sequence system. After long-term practice, the sequential procedure can be produced largely by the action sequence system, which can produce the sequence directly without visual-to-motor translation.

These two learning systems are supported by two subsystems, one for reinforcement learning (basal ganglia) and the other for motor sequence learning (cerebellum). The reinforcement learning system acts to decide whether the performed sequence is to be learned based on the reward outcome of the procedure. The motor se-

quence system acts to refine and coordinate individual movements based on timing information.

The model obviously is incomplete but provides a working scheme to consider possible ways in which the brain works in a goal-directed manner because the brain, after all, is composed of parallel, distributed neural networks.

ACKNOWLEDGMENTS The authors thank Makoto Kato for designing the computer programs for animal experiments, Kenji Doya for providing valuable advice in theoretical approaches, and Satoru Miyauchi, Ryosuke Takino, Yuka Sasaki, and Benno Pütz for contributing to the fMRI experiments.

NOTES

1. Abbreviations: dorsolateral prefrontal cortex (DLPF), pre-supplementary motor area (pre-SMA), supplementary motor area (SMA), intraparietal sulcus region (IPS), premotor area (PM), frontal eye field (FEF), supplementary eye field (SEF), primary motor cortex (M1).
2. The DLPF is crucial for various processes for working memory (Goldman-Rakic, 1996), including coding of behavioral sequences (Petrides, 1995). However, it seems unlikely that DLPF stores event sequence information as a long-term memory. Such a long-term memory function may be carried out by other brain areas, perhaps including the precuneus or the intraparietal areas (Sakai et al., 1998).
3. Many studies have suggested that motor sequences are coded by neurons in the SMA (Tanji and Shima, 1994) and that the human SMA is activated with learning of motor sequences (Jenkins et al., 1994; Petersen et al., 1998). Our studies also suggest the SMA is related to anticipatory expression of learned motor sequences (Miyashita et al., 1996).
4. The pre-SMA receives inputs from the DLPF (Luppino et al., 1993) which may carry information on event prediction, and from the posterior parietal cortex (Luppino et al., 1993), which may carry current visual inputs.
5. The PM appears to be related to the visuomotor coordinate transformation, as shown by visually guided actions (Passingham, 1985; Rizzolatti et al., 1996), action recognition (Gallese et al., 1996), and object-centered visual responses (Graziano, Hu, and Gross, 1997).
6. Pre-SMA neurons tend to decrease activity as the number of errors decreased with learning (Nakamura, Sakai, and Hikosaka, 1998; Sakai et al., 1998).
7. Note that, after the action sequence system starts learning, the event sequence system would continue to learn the visual sequence to store it as a long-term memory, perhaps outside the DLPF.
8. The SMA may be learning a motor sequence while the performance still is guided by visual inputs (i.e., relative early stage of long-term learning, as our study suggested) (Nakamura, Sakai, and Hikosaka, 1998).

9. Many studies have suggested that the cerebellum is related to the timing process (Ivry and Keele, 1989; Jueptner et al., 1996).
10. Our unpublished observation (Sakai et al., 1999) using fMRI indicates that the posterolateral part of the cerebellum is activated selectively when the timing of response is uncertain, whereas the pre-SMA is active when the kind of response is uncertain. Conversely, it still is unknown whether the anterior cerebellum is involved in storage of timing information.

40 The Superior Colliculus and the Cognitive Control of Movement

ROBERT H. WURTZ, MICHELE A. BASSO, MARTIN PARÉ, AND MARC A. SOMMER

ABSTRACT Normal vision consists of an alternation of saccadic eye movements and periods of visual fixation. This is a relatively simple alternation of movement and nonmovement, but the control of this alternation involves many of the cognitive issues underlying the performance of more complex actions. The superior colliculus (SC) is a nexus in the brain system controlling these saccades and fixations, and recent experiments have shown how this structure and its cortical inputs contribute to their control. Activity on the SC movement map shows that the amplitude and direction of the impending saccade is most likely to be represented by the vector average across a large population of neurons. The control of the alternation of movement and nonmovement, which in the case of the saccadic system is the alternation of saccades and fixation, involves the balance of competition between SC neurons tonically active during visual fixation (fixation neurons) and those active long before saccades (buildup neurons). The preparation to move may be represented by the long lead or delay activity of buildup neurons because, as the probability that a saccade will be made increases, this delay activity increases. Whether the processing preceding movement initiation is discrete for each area or is distributed across areas can be answered by comparing neuronal activity in the SC with that of the neurons in frontal and parietal cortices that project to the SC. The processing is distributed with overlap between neuronal activity in cortex and SC and a shift in the SC toward movement preparation.

Rapid or saccadic eye movements shift our line of sight from one part of the visual field to another and allow us to direct the higher visual acuity provided by the fovea toward successive points in the field. We make these eye movements as frequently as two times per second during such tasks as scanning the visual scene or reading. Just as important as the saccades, however, is the lack of movement between them because it is in these periods of fixation when almost all vision occurs. Thus, saccades and fixations can be regarded as an integrated system that both moves the eye rapidly to the next target and then holds the eye steadily on that target. This alternation of saccades and fixation is particularly evident during reading (figure 40.1).

Even given that saccades and fixation are necessary for normal vision, why should such a relatively mechanistic system be of any relevance to cognitive neuroscience? There are at least three reasons.

First, saccades are relatively simple movements, and they therefore offer the opportunity to understand a simple system within the brain for generating actions. The saccades involve rotation of each eye by the coordinated activation of only six muscles, have no variation of load—and therefore have no need for load compensation—and have no complexity introduced by the movement of joints (Robinson, 1968). These relatively simple movements do, however, involve most of the cognitive issues underlying the performance of more complex actions. For example, a saccadic eye movement to a visual stimulus requires shifting attention and selecting a target, transforming input from a sensory map to the output on a movement map, and then coordinating the appropriate muscles to execute the movement and hold the eye in the new position.

Second, we have a superb animal model of the human saccadic-fixation system in the old-world monkey, which allows us to study the brain mechanisms controlling the movement. Since the introduction of the now standard techniques for recording neuronal activity from awake behaving monkeys (Evarts, 1966), the accurate recording of eye movements (Fuchs and Robinson, 1966; Judge, Richmond, and Chu, 1980), the training of monkeys to control eye movements (Fuchs, 1967), and the visual stimuli that guide them (Wurtz, 1969), the regions of the monkey brain active before visually guided saccades have been identified. The visual pathway to the striate cortex, to extrastriate areas, and then to the regions of the parietal and frontal cortices have been identified and are included in figure 40.2A. Just as the elaboration of the changes in visual processing at each step in this pathway has contributed to our understanding of the visual input on which further cognitive processing is built, the extensive understanding of the brainstem oculomotor centers for saccade generation (Hepp et al., 1989; Moschovakis and Highstein, 1994) has led to greater understanding of what output is required of cognitive

ROBERT H. WURTZ, MICHELE A. BASSO, MARTIN PARÉ, and MARC A. SOMMER Laboratory of Sensorimotor Research, National Eye Institute, National Institutes of Health, Bethesda, Md.

FIGURE 40.1 Interplay between rapid eye movements (saccades) and the pauses between these movements (fixation). In this example of the successive eye positions during the reading of a single line of text, saccades (vertical lines) move the eye across the page but are separated by periods of visual fixation (horizontal lines). Almost all of visual perception occurs during these periods of visual fixation. (Modified from Yarbus, 1967.)

processing for movement generation. Understanding the “spinal cord” for the saccadic system allows us to step backward gradually from the basic mechanics of movement to consider the control of these actions at higher levels.

Third, there is a nexus in the system through which much (although not all) of the information from the cortex flows to the brainstem oculomotor structures, the superior colliculus (SC). The SC receives inputs from the parietal and frontal areas of the cerebral cortex known to be related to saccade generation both directly and through the basal ganglia (Fries, 1984; Hikosaka and Wurtz, 1983) (figure 40.2A) and projects directly to the pontine and midbrain oculomotor areas. The SC can be viewed as a location for the coordination of the varied inputs from the forebrain and as the location for the transformation of these into outputs for the control of movement. It is the last step in the system in which both a visual and a motor map clearly are evident (Robinson, 1972; Schiller and Stryker, 1972; Wurtz and Goldberg, 1972).

In this chapter, we concentrate on several recent developments of our understanding of the saccadic/fixation system and its relation to the control of movement. We first describe how the neuronal elements in the SC are organized, including how only a few neuron types can be organized across a map to provide different output signals. Then we consider how the SC contributes to the alternating pattern of saccades and fixations. Finally we consider the “delay” activity between the neuronal response to the stimulus and the burst before a saccade and consider the transition leading to this activity in the cortical neurons that project to the SC.

FIGURE 40.2 Brain systems for the generation of saccades and fixation. (A) Outline of the pathway from the visual input through cerebral cortex to oculomotor centers controlling eye muscles. The schematic drawing shows a lateral view of a monkey brain. The afferent visual pathway is indicated by the dotted line arrows passing from the retina to the lateral geniculate nucleus (LGN) of the thalamus to the striate cortex (V1), and then by a series of steps (not shown) to the parietal cortex (the lateral intraparietal [LIP] area) and the frontal cortex (the frontal eye field [FEF]). The projections from these areas to the superior colliculus (SC) are indicated by the solid line arrows. Omitted from the drawing are several areas (including the supplementary eye field in frontal cortex), reciprocal connections between areas, and the indirect pathway through the basal ganglia (caudate and substantia nigra pars reticulata). The output from the colliculus to the midbrain and pons oculomotor centers and then to the eye muscles also are indicated by dotted lines. (B) The schematic drawing of the organization of the SC on the right and left sides of the brain. Small saccades are represented in the rostral SC (0°) and large saccades are represented in the caudal SC (40°). The activity before a saccade is across a population of neurons, which is represented by a mound in the SC on the side of the brain opposite to the direction of the impending saccade.

Organization of the superior colliculus

The SC lies on the roof of the midbrain and consists of successive gray and white layers. Neurons in the superficial layers respond to visual stimuli and have receptive fields in the field contralateral to their location in the SC. Neurons in the intermediate layers often also respond to visual stimuli, but their most vigorous discharge is before the onset of saccadic eye movements.

We concentrate on these saccade-related neurons because it is in them that we see the transition from sensory to motor-related activity.

SUPERIOR COLLICULUS MAP FOR SACCADDES Just as superficial-layer neurons have visual receptive fields, the saccade-related neurons in the intermediate layers have movement fields, that is, they increase their activity before saccades made only to one region of the visual field (Wurtz and Goldberg, 1972). There is a gradient of activity within each movement field, and a neuron's maximum discharge is associated with saccades of specific amplitude and direction—the neuron's optimal saccadic vector. Different neurons have different vectors, and the neurons are organized in a highly regular fashion to produce a neural map of saccadic vectors covering the contralateral visual field (figure 40.2B). On this map, large saccades are represented in the caudal portion, small are in the rostral region, upward are more medial, and downward are more lateral.

NEURON TYPES The activity of all the neurons within the intermediate layers is not identical, however, and to systematically study them, different types have been identified. The classification we use (Munoz and Wurtz, 1995a) is based largely on the activity of these neurons that comes *after* any initial visual response to the saccade target but *before* any burst of activity preceding saccade onset. This intervening activity is best revealed in two behavioral paradigms, the visual and memory-delayed saccade tasks. In these delay tasks, there is a period of active fixation during which we measure the resting discharge rate of the neuron. Then a visual target is presented in the center of the neuron's movement field, but the monkey is required to delay making a saccade to it (the delay period) until the fixation stimulus is extinguished (the cue to move). In the visual task, the target remains until the end of each trial, whereas in the memory task, it is only flashed and the monkey has to make a saccade to the remembered location.

Burst neurons (Munoz and Wurtz, 1995a) are the saccade-related neurons that have been most extensively studied in the SC and those that also have been referred to as saccade-related burst neurons (Sparks, 1978). In the delayed saccade tasks, these neurons frequently display a brief response time-locked to the onset of the visual stimulus, but their salient response is the vigorous burst of activity before a saccade made into their movement field (figure 40.3A). In contrast to other saccade-related neurons, they have next to no discharge during the delay period. The burst neurons are found throughout the rostral to caudal extent of the collicular map, and it is assumed

that their activity is a signal to make a saccade with a vector coded by the position of that neuron on the SC map.

Buildup neurons continue to show sustained activity during the delay period in a delayed saccade task (figure 40.3B). In contrast to the burst neurons, these neurons do not necessarily show a discrete saccade-related burst in activity and certainly must include many, if not all, of the saccade-related neurons other than the burst neurons that have been described in many experiments, beginning with the earliest investigations (Mays and Sparks, 1980; Mohler and Wurtz, 1976; Sparks, 1978; Wurtz and Goldberg, 1972). Because of their delay activity, they originally were referred to as long lead neurons (Sparks, 1978). Munoz and Wurtz (1995a) more recently categorized these neurons as *buildup* neurons because their delay activity often increases gradually as the saccade onset approaches. Note that this neuronal class also may include neurons that were described differently by other groups, for example, quasi-visual neurons (Mays and Sparks, 1980) and prelude bursters (Glimcher and Sparks, 1992). Like the burst neurons, the buildup neurons are found throughout the collicular map. Our working hypothesis is that their buildup or delay activity represents the preparation to make a saccade, and their activation may facilitate saccade production.

Fixation neurons become active tonically when the animal fixates a visual stimulus and pause when a saccade occurs (figure 40.3C). These neurons originally were described in the cat SC (Munoz and Guitton, 1991) and then were identified in the monkey (Munoz and Wurtz, 1993a). In the monkey, the fixation neurons were shown further to sustain their discharge when the fixation stimulus was removed and the monkey continued to fixate, thereby ruling out the possibility that these neurons were simply visual neurons with a foveal receptive field excited by the fixation stimulus. The fixation neurons are found in the rostral region of the SC on both sides of the brain. Their discharge is related to the maintenance of fixation.

CONCLUSION: SUPERIOR COLLICULUS ORGANIZATION It is striking that there may be only a few neuron types within the SC intermediate layers although there may be more variation, particularly among the buildup neurons, than we consider here. The two points to be emphasized on the organization, however, are not new but rather have been recognized for a number of years. First, the map of saccadic vectors, which we have described (see review by Sparks and Hartwich-Young, 1989), conveys the vector for the *change* in eye position produced by the saccade. Second, a change in the activity of a *population* of neurons on the SC map has significant importance, which we

FIGURE 40.3 Classification of neurons in the intermediate layers of the SC into three categories: burst, buildup, and fixation. The top row of each example shows the eye position traces, and below these are rasters, with each tick in the raster representing a single action potential and each row of ticks representing a single trial. The superimposed spike density functions show the sum of the activity across the trials. All traces are aligned on the onset of the saccadic eye movement. (A) An example of a burst neuron with a clear response to the onset of the visual target (start of the line) and a burst of activity before the saccade (arrowhead under the line). (B) An example of a buildup neuron with a slight visual response, continuing activity, and a burst of activity before the saccade. Buildup neurons can be defined as those whose discharge rate during the delay period is significantly higher ($P < .01$) than the resting rate. While the buildup neurons clearly are different from the burst neurons, they may form a continuum with them; the buildup neurons also may be a more heterogeneous as suggested by the broad range of discharge behaviors exhibited in response to the visual stimulus and before the saccade. (C) An example of a fixation neuron with a high rate of discharge while the monkey is fixating on a target.

Interaction of saccades and fixation

One of the striking observations on the SC is the identification of neurons that are related to both the generation of saccades and the maintenance of fixation.

CONTINUITY OF FIXATION AND BUILDUP NEURONS
Fixation neurons have been described as a separate class of neurons because of their high discharge rate during fixation, and understanding how they are related to other SC neurons depends on determining what controls their high rate of discharge during active visual fixation. One possibility is that the discharge of these fixation neurons could be influenced by factors similar to those influencing the buildup neurons because although we have described the buildup and fixation neurons as behaving very differently (figure 40.3), they have at least two characteristics in common. First, they both lie somewhat deeper in the SC than the burst neurons (Munoz and Wurtz, 1995a). Second, they both have movement fields; most fixation neurons, like buildup neurons, were shown to have a burst of activity with small contralaterally directed saccades (Munoz and Wurtz, 1995a).

One possibility is that the fixation neurons have delay activity just as buildup neurons do, and that the increased activity during fixation essentially is this delay activity. To investigate this, Krauzlis and associates (1997) recorded from neurons in the rostral SC that had the characteristics of fixation neurons, including continued discharge when the monkey fixated in the absence

have not yet emphasized. Before the onset of a saccade, it is not just a few neurons that become active but roughly 25% of the entire population (Munoz and Wurtz, 1995b), and it is the vector average of these active neurons that appears to determine which saccade is made (Sparks et al., 1990), as represented by the mound of activity on the SC map in figure 40.2B.

FIGURE 40.4 Fixation neuron activity with small changes in target position. (A) Changes in firing rate of a neuron after small steps of the fixation target into the visual field either ipsilateral or contralateral from the SC in which the neuron was recorded. Symbols show the mean firing rate over an interval beginning 100 ms after the target step and lasting for 100 ms or until 8 ms before the saccade onset. Error bars indicate ± 1 SD for the 12 trials. The dotted line indicates the percentage of trials on which each target step elicited a saccade. Dashed line indicates the mean firing rate with no target steps. (B) Change in activity of four fixation neurons from one monkey after the same small steps. The four have been normalized so that the peaks of the curves are 100. The neuron with the darkened trace is the same as in (A). (From Krauzlis and associates, 1997)

of a fixation target. They stepped the target on which the monkey was fixating to slightly eccentric locations and rewarded the monkey for making a saccade to the target. Fixation neurons showed the largest increases in firing rates with small steps into the contralateral visual field; the neuron in figure 40.4A showed the largest response for steps of approximately 0.5° . Different neurons showed the maximal response for contralateral steps of different sizes (figure 40.4B). Saccades to large target steps were accompanied by a decrease in activity for both ipsilateral and contralateral saccades, as had

been reported previously (Munoz and Wurtz, 1993a). What is particularly relevant is that the increase always was for small steps and that the increase in activity occurred whether the step elicited a saccade or not. Krauzlis and colleagues (1997) concluded that the fixation neurons are tonically active during visual fixation, not because they are carrying a unique fixation signal but because they are indicating target locations very close to the fovea that usually do not elicit a saccade.

What these experiments show is that the activity of the fixation neurons during fixation has two striking similarities to the delay activity in buildup neurons. First, both the fixation and buildup neurons increase their activity for a target at some eccentricity in the contralateral visual field, the fixation neurons for very small target steps and the buildup neurons for larger steps. Second, the delay activity is present even if no saccade is made, as indicated for the fixation neurons by Krauzlis and associates (1997) and for the buildup neurons by Munoz and Wurtz (1995a). Thus, the fixation neurons might be regarded most parsimoniously as a rostral continuation of the buildup neurons. The hypothesis that emerges is that the activity of these fixation and buildup neurons indicates an error between where the eye is and where the target is, and the size of the error represented by the neuron depends on the location of the neuron on the SC movement map. This simplification eliminates the problem of deciding where in the rostral SC the fixation cells end and where buildup neurons begin. The different effects of activating these neurons depends on their interactions within the SC and probably their differential connections outside the SC, as we consider in the next section.

FIXATION AND SACCADIC INTERACTION How does this proposed continuity of fixation and buildup neurons affect the original hypothesis (Munoz and Wurtz, 1993a, 1993b) that the activity of monkey fixation neurons suppresses the generation of saccades? We believe that the interaction between saccades and fixation still is controlled by a system within the brain that includes the SC but that the observations just described show how the neuronal elements are organized to carry out this interaction. The basic observations on the effects of activating or inactivating the rostral SC still hold. Saccades are suppressed by the activation of the SC fixation region by either electrical stimulation or injection of the chemical agent bicuculine, a gamma-aminobutyric acid (GABA) antagonist (Munoz and Wurtz, 1993b). Conversely, saccade production is facilitated by the inactivation of the fixation neurons by injection of the GABA agonist muscimol (Munoz and Wurtz, 1993). Both observations show that alteration of the rostral SC affects when saccades are generated.

FIGURE 40.5 Mutual inhibition of fixation and buildup neurons. The arrows indicate inhibitory interactions. The fixation neurons in the rostral SC inhibit the saccade-related neurons in the caudal SC whereas the saccade-related neurons inhibit both other saccade neurons and the fixation neurons. Not shown are the inhibitory inputs from the basal ganglia or the presumed excitatory inputs from cerebral cortex.

This leads to a hypothesis of the interaction between fixation and saccades shown schematically in figure 40.5. The basic assumption is that when any population of SC neurons is active anywhere on the SC map, they suppress the activity of all other SC neurons. When buildup neurons in the caudal SC become active, they act to inhibit all other neurons in the SC, including the most rostral fixation-type buildup neurons. They also provide an error signal according to their position on the SC, indicating which saccadic vector would be required to bring the eye to the target to eliminate the error. The output of these neurons may be to adjacent burst neurons as well as directly to neurons in the pons and midbrain outside the SC. When the fixation neurons in the rostral SC become active, they also inhibit all other SC neurons. The fixation activity also indicates that a position error exists, but this error signal is so small that no eye movement is elicited—giving incidentally a physiological basis for the concept of a dead zone for saccade initiation (but considerably larger than that in humans) (Wyman and Steinman, 1973). The outcome of this competition for fixation or saccade (here and probably in other parts of the brain as well) determines the initiation of saccades. There may be differences in the strength of the inhibitory effects in the rostral and caudal regions of the SC, but the neural mechanisms can be regarded as fundamentally the same.

Several lines of evidence are consistent with the interactions between rostral and caudal SC, as outlined in figure 40.5. First, it has become clear that activity in the rostral SC does directly inhibit saccade-related neurons in the caudal SC. Initially, the saccade suppression effect caused by the activation of the SC fixation region logi-

cally could be explained by an interaction between fixation and saccade-related elements located downstream of the SC. Indeed, a pause in the activity of brainstem omnipause neurons is necessary to release the burst generator and produce a saccade (Hepp et al., 1989; Moschovakis and Highstein, 1994), and these neurons receive preferential projection from the rostral SC (Büttner-Ennever and Horn, 1994; Paré and Guitton, 1994). The SC fixation neurons therefore could alter the generation of the saccade as an influence onto the activity of omnipause neurons, that is, without acting directly on the SC saccade-related neurons. Munoz and colleagues (1996), however, showed that when electrical stimulation of the rostral SC interrupts saccades in mid-flight, there is a pause in the saccade-related activity of both burst and buildup neurons in caudal SC when the eyes stop momentarily. This indicates that the fixation neuron activity does act on the SC saccade-related activity.

The mutual inhibitory effect of activity in the rostral and caudal SC also has received support from both physiological and anatomic experiments. By electrically stimulating within the monkey SC, Munoz and Istvan (1998) established the inhibitory effect of fixation neurons on burst and buildup neurons and of these saccade-related neurons back onto fixation neurons. In addition, these experiments showed that stimulation of saccade regions also inhibits other remotely located saccade-related neurons. (The only exception to the mutual inhibition between collicular neurons is the connection between the fixation neurons in the two SCs: stimulation of one fixation region excites rather than inhibits the fixation neurons in the other SC.) The presence of GABAergic connections throughout the SC (Mize, 1992) and the recent experiments in the ferret (Meredith and Ramoa, 1998) showing that stimulation at any point in the SC, rostral or caudal, produces an initial inhibition at distant points in the SC, support the hypothesis of inhibitory interactions. Behan and Kime (1996) showed in the cat that biocytin injections label cells within 0.5 mm up to 5.0 mm from the injection site, which provides anatomic evidence for horizontal connections throughout the length of the SC. Thus, the mutual inhibition between different parts of the SC, consistent with the fixation/saccade interactions within the SC, are supported by what is known about the physiological and anatomic connections between these neurons.

EXPRESS SACCADDES The interaction between fixation- and saccade-related activity has been explored in a recent series of experiments on an express saccade, a short latency saccade that is critically dependent on an intact SC (Schiller, Sandell, and Maunsell, 1987). These exper-

iments illustrate most clearly the interactions we have considered.

One of the most prominent ideas about the shift in fixation caused by a saccade, which usually is addressed with respect to the accompanying shift of attention, is that there must be an initial disengagement from the current fixation stimulus. This disengagement also was proposed to be critical in the reduction of saccadic reaction time in the gap saccade paradigm and the generation of express saccades (Fischer and Weber, 1993), the latencies of which (~80 ms) approach the conduction time from the retina to the eye muscles (Fischer and Boch, 1983). With the discovery of the SC fixation neurons, a neural correlate for the fixation disengagement was obvious: the disengagement occurs when the fixation neurons reduce their discharge after the disappearance of the fixation stimulus or pause before saccades. The increased incidence of express saccades following rostral SC inactivation (Munoz and Wurtz, 1991) provided experimental support for this hypothesis, as did the finding that a decrease in fixation activity during the gap task correlates with the reduction in saccade reaction time (Dorris, Paré, and Munoz, 1997).

Recording of the activity of SC burst neurons revealed that the saccade-related burst of activity is indistinguishable from the target-related responses of these neurons when an express saccade is produced (Dorris, Paré, and Munoz, 1997; Edelman and Keller, 1996). It was hypothesized that the release of fixation permits the target-related responses of SC neurons to be strong enough to trigger short-latency express saccades (Edelman and Keller, 1996; Sommer, 1994).

Fixation disengagement, however, can only be a part of the mechanism for express saccades in the monkey, as indicated by recent behavioral experiments by Paré and Munoz (1996). Using the gap saccade task, they trained monkeys to make express saccades after presenting the saccade target repeatedly in the same part of the visual field. After this training, express saccades were made only to a restricted region of the visual field centered on the location of the target used for training. The disappearance of the fixation stimulus before target presentation did not lead to express saccade production at the other target locations but simply reduced the mean saccadic reaction time. Overall, these results indicate that it is the neuronal activity associated with the preparation to make saccades to the training target that determines the occurrence of express saccades, not just the release of fixation afforded by the disappearance of the fixation stimulus. In subsequent physiological experiments, Dorris, Paré, and Munoz (1997) showed that fixation neurons decrease their discharge before express saccades, but that these changes are not predictive of ex-

press saccade production (figure 40.6A). In contrast, the increased level of discharge of buildup neurons before target presentation was found to be correlated with the occurrence of express saccades when these were made into the movement field of the neurons (figure 40.6B). This increase in the early activity of buildup neurons thus may facilitate the excitability of the corresponding saccade region and thereby allow the target-related responses of the SC neurons to trigger the short-latency express saccades. Additional evidence for this motor preparation hypothesis for express saccade generation comes from another behavioral study. Using a scanning saccade paradigm, Sommer (1997) compared the spatial attributes of saccades produced in response to suddenly appearing stimuli with those made while scanning to unchanging stimuli. He found that the occurrence of express saccades was related to the congruence between the location of the suddenly appearing target and the goal of voluntary saccade planning.

If we generalize the observations made on express saccade generation to all saccades, the decision to make a saccade can be reduced to the competitive interaction between the signals related to planning a saccade and those related to maintaining fixation. Each signal is necessary, but not sufficient, for determining when a saccade will be initiated.

CONCLUSION: SACCADIC AND FIXATION INTERACTION The observations described emphasize several points. First, the interactions underlying the alternation of fixation and saccades all may depend on interactions between *one neuronal class* in the SC, what we have referred to as the buildup neuron. This illustrates a case in which one neuronal element can be used to produce quite different effects (fixation or saccades) depending on its relation to other neurons on a neuronal map. Second, the movement generation is a result of *the balance of competition* between the activity of the neurons signaling movement (the buildup neurons and probably the burst neurons as well) and those signaling nonmovement (the fixation neurons). This interaction is based on competing activity on two parts of the SC map (rostral fixation and caudal saccade), and the outcome determines when a saccade will be made.

Superior colliculus delay activity

The SC activity that we have concentrated on in considering fixation is the activity in the delay period that precedes the burst of activity accompanying saccades. Following, we consider factors that alter this delay activity.

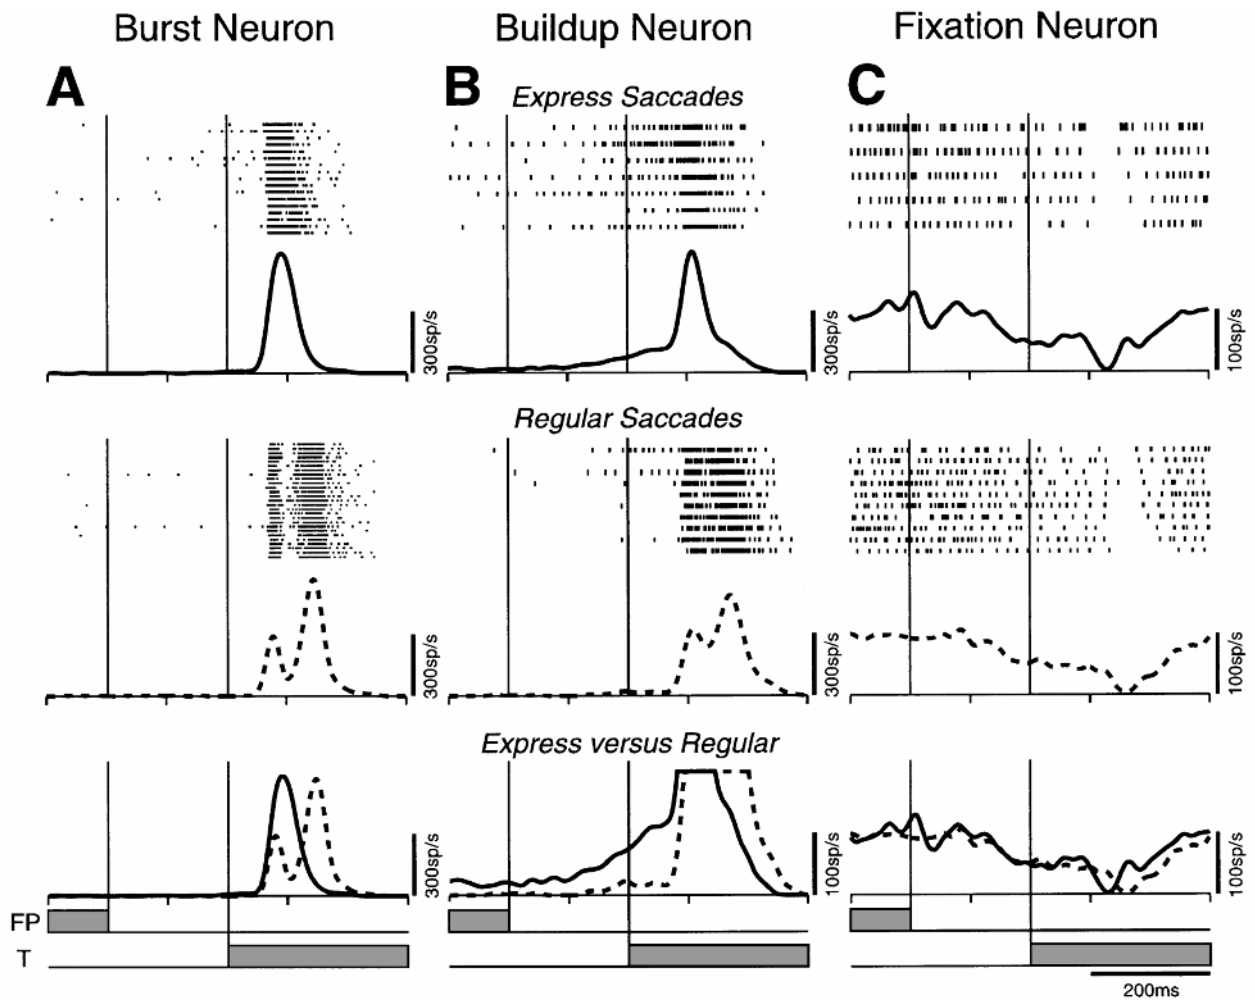

FIGURE 40.6 Neuronal activity of burst (A), buildup (B), and fixation (C) neurons during the generation of short-latency express saccades (top) and long-latency regular saccades (middle). The paradigm used was the gap saccade task in which the fixation stimulus (*FP*) is extinguished 200 ms before the target (*T*) presentation (as indicated by the bars along the bottom). Rasters and spike density functions are aligned on target onset. In the bottom panel, the spike density functions of the express (solid line) and the regular (dashed line) trials are superimposed. (A) The activity of burst neurons displayed two bursts before regular saccades: one time-locked to the target onset and a later one time-locked to the saccade onset. In contrast, express saccades were preceded by only one robust

burst time-locked to both target and saccade onsets. (B) The discharge rate of buildup neurons during the gap period before the target onset was greater for express saccade trials compared with regular saccades. After the target presentation, the buildup neuron showed activity similar to the burst neuron. (C) The activity of fixation neurons decreased during the gap and paused just before either express or regular saccades. However, the level of activity associated with each type of saccades did not differ. Express saccades were defined as those with latencies between 70 to 120 ms, and regular saccades had latencies between 130 and 180 ms. (After Dorris, Paré, and Munoz, 1997.)

Because this delay period activity is not tied to the occurrence of the saccade, Munoz and Wurtz (1995a) proposed that it represents the preparation to make a saccade. Consistent with this motor preparation hypothesis, Dorris and colleagues (1997) demonstrated that the level of delay activity for a significant proportion of buildup neurons (41%) predicts motor performance. They showed that the level of buildup activity during a gap period (between the time the fixation

stimulus was turned off but before presentation of the target) was inversely correlated to the reaction time of the saccade: the greater the discharge, the shorter the reaction time.

If these early neuronal changes are related to preparation to make a saccade, then such changes should be sensitive to the likelihood that a saccade will be made (Riehle and Requin, 1993). Two recent experiments tested whether manipulating the prior knowledge of the

monkey as to whether a saccade will be made alters the delay activity of the SC buildup neurons.

TARGET PROBABILITY PARADIGMS Basso and Wurtz (1997, 1998) used two paradigms that required monkeys to make a saccade to a peripheral stimulus while changing the probability that a given stimulus would be the saccade target.

In the first paradigm, varying the number of stimuli presented to the monkey changed the probability that the one located in the movement field of the neuron would become the target. One, two, four, or eight stimuli were presented, and then later the monkey was cued as to which one was the saccade target (figure 40.7). During the preselection period, when the monkey did not know which of the stimuli would be the target, increasing the number of possible targets from one to eight decreased the activity. When the target dimmed, the activity in each condition increased to the level present when only a single target was present. During the preselection period, the mean discharge rate of all buildup neurons studied decreased as target probability decreased.

In a second paradigm, the number of stimuli remained constant so that no changes related to visual interaction could account for the results. Presenting the eight targets in a series of blocked trials, in which the same one of the eight stimuli became the target, increased target probability. After a number of trials, the neurons developed a higher level of activity than in the case when any of the eight stimuli could become the target. Therefore, changes in target probability modulate the buildup activity during a delay period whether those changes result from varying the number of stimuli or varying the monkey's previous experience. In contrast, the burst of activity of burst neurons and the saccade-related burst activity of buildup neurons did not change in either probability experiment.

GO/NOGO PARADIGM In this experiment, the fixation stimulus provided information about whether a saccade would be required to a peripheral stimulus located in the movement field of the neuron. In the two types of trials used, the fixation stimulus first changed color, signaling to the monkey that the upcoming peripheral stimulus should be either ignored (Nogo trials) or should be taken as the target for a saccade (Go trials—see stimulus bars in figure 40.8). Most buildup neurons tested in this paradigm (61%) showed delay activity specific to the Go instruction, as exemplified in figure 40.8 (Sommer, Paré, and Wurtz, 1997). For these neurons, the buildup activity was much higher after target pre-

sensation if the Go instruction was provided, that is, if a saccade was to be executed. For the sample of buildup neurons ($n = 62$), the delay activity in Go trials was 2.4 times greater than that observed in Nogo trials. Other studies have demonstrated similar modulation of early low-frequency discharge in SC neurons in tasks designed to show activity changes with movement selection (Glimcher and Sparks, 1992) or shifts in attention (Kustov and Robinson, 1996).

CONCLUSION: DELAY ACTIVITY Both the target probability and the Go/Nogo experiments show that a greater probability that the monkey will be required to make a saccade on a particular trial leads to a higher level of delay or buildup activity. This increase is consistent with viewing the buildup neuron activity as part of the preparation to make a saccade that precedes the burst of activity at the time of a saccade. This increased activity that precedes the generation of a saccade represents an increase in activity on one part of the SC map, and this activity develops over time during the delay period. We believe that what we refer to loosely as “preparation to move” might best be regarded as the gradual specification over time of one part of the SC map as the center of activity for the next saccade. This localized activity specifies the vector for the next saccade, and the narrowing of activity over time is a narrowing of the selection of this vector.

Cortical input to superior colliculus

Many of the fixation, buildup, and burst neurons are likely to receive input from the cerebral cortex. This opens the possibility of seeing the transition in activity between the cerebral cortex and the superior colliculus. To explore this transition, the cortical neurons that project to the SC must be identified. It is not sufficient to compare the activity of any neuron in the cortical areas that project to the SC with the SC activity because many of the cortical neurons might not project to the SC. We need to study specifically those neurons that project to the SC and have used antidromic stimulation to do so. In this technique, a cortical neuron is identified as projecting to the SC if electrical stimulation of the SC produces spikes in the cortical neuron with short consistent latencies (along with other criteria, Lemon, 1984). We have concentrated on the neurons in the parietal and frontal cortex because neurons in these regions have well-established projections to the SC (Huerta, Krubitzer, and Kaas, 1986; Leichnetz and Goldberg, 1988; Lynch, Graybiel, and Lobeck, 1985).

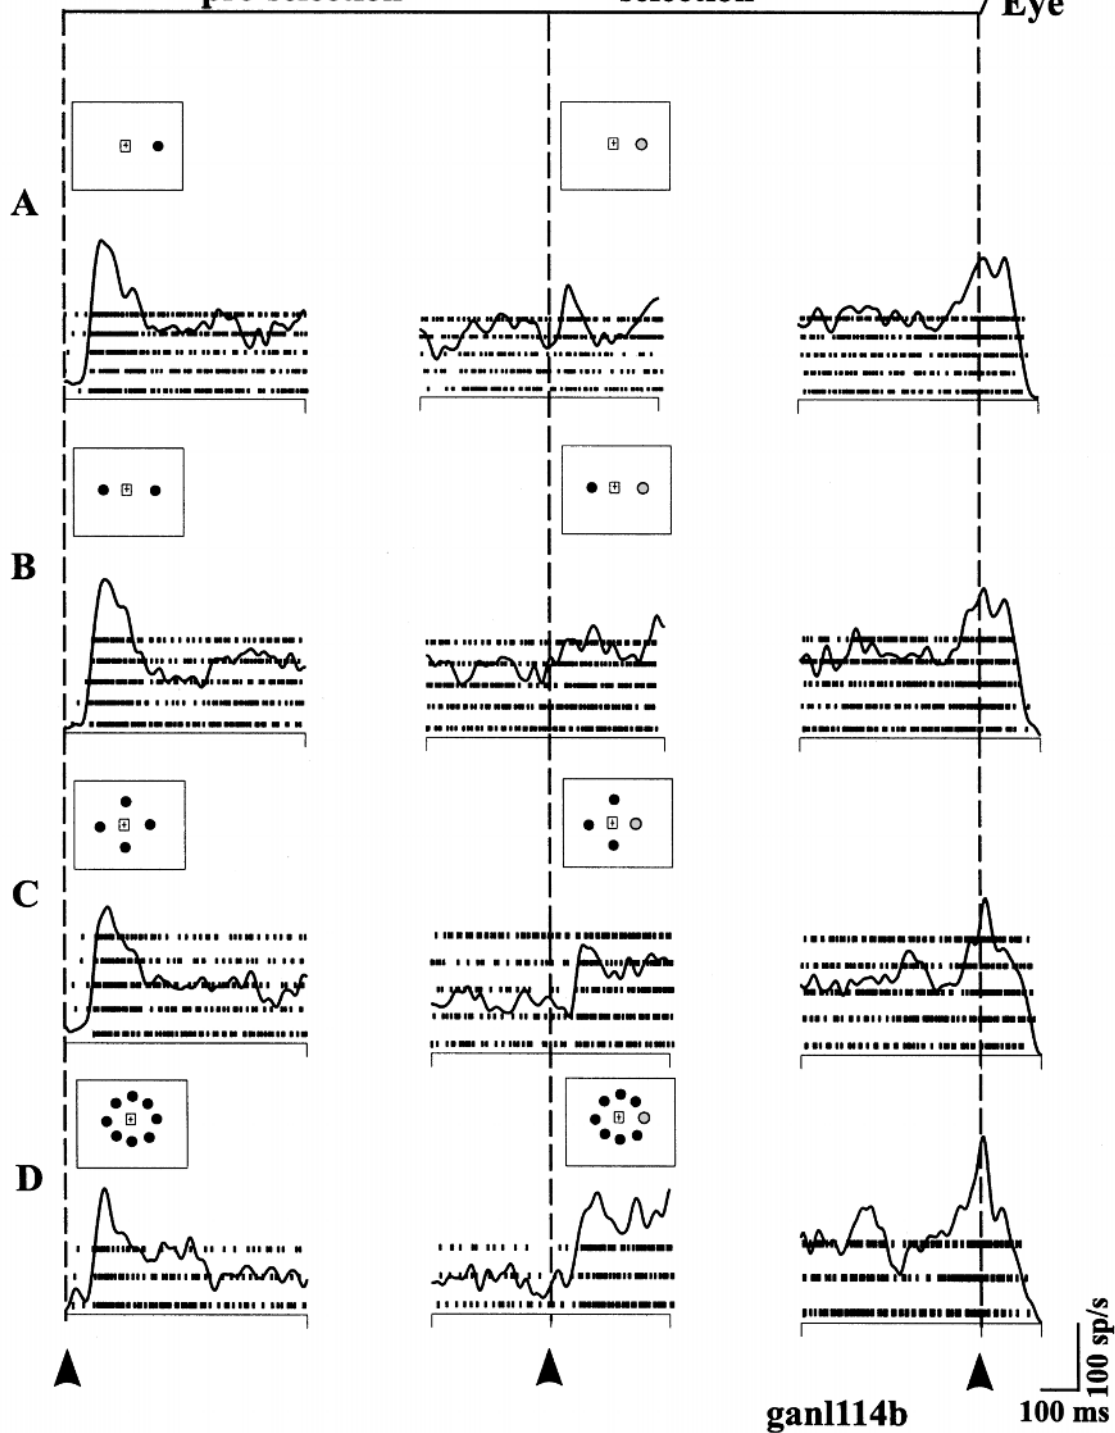

FIGURE 40.7 Buildup neuron activity modulated by shifts in target probability. Increases in the number of potential targets for the impending saccade reduced buildup neuron activity. The events of the task are indicated by the labeled periods of time across the top, and the spatial arrangement is indicated by a schematic of the stimulus display in front of the monkey. The first column shows activity on five trials in the rasters and the mean of these in the superimposed spike density trace when one (A), two (B), four (C), or eight (D) targets were presented during the preselection. This example is taken from trials when the target was in the movement field of the neuron. The first column is aligned (vertical dashed lines) on the onset of the possible targets (preselection period), the second on the dimming of one of the targets (selection period), and the third on the onset of the saccade (eye movement period). There is an initial visual response and subsequent sustained or delay period activity. Both of these activities were reduced as the number of stimuli was increased. When the target dimmed, the activity increased. This neuron had a burst of action potentials associated with the onset of the saccade that did not differ substantially between the probability conditions.

PARIETAL CORTEX INPUTS TO SUPERIOR COLLICULUS The lateral intraparietal (LIP) area is the area in the inferior parietal lobule where saccade-related activity has been described by both the Andersen and Goldberg groups (Andersen and Gnadt, 1989; Andersen, Essick, and Siegel, 1987; Barash et al., 1991; Colby, Du-

hamel, and Goldberg, 1995; Colby, Duhamel, and Goldberg, 1996; Mazzoni et al., 1996). Paré and Wurtz (1997) first identified the LIP neurons that can be activated antidromically from electrical stimulation within the SC. The projection neurons act primarily on the intermediate layers of the SC because antidromic activation thresholds reached minimum values at depths where neurons showed saccade-related activity. The LIP projection to the SC appears to be organized topographically because the most efficient antidromic stimulation typically was obtained at SC sites with movement fields similar to those of the LIP neurons.

Approximately 75% of the identified LIP efferent neurons responded to the onset of the visual target, and approximately 60% of the neurons maintained their activity during the delay period of either the visual or memory-delayed saccade tasks. Several LIP neurons also exhibited a modest saccade-related increase in activity, but none had only a saccade-related burst of activity like the SC burst neurons or some frontal eye field (FEF) efferent neurons. Although the LIP neurons therefore were more similar to the SC buildup neurons than to the SC burst neurons, the LIP neurons differed from the SC neurons in the Go/Nogo task (figure 40.9A). Only about one third of the LIP efferent neurons had delay activity that occurred only after the Go instruction, and the mean

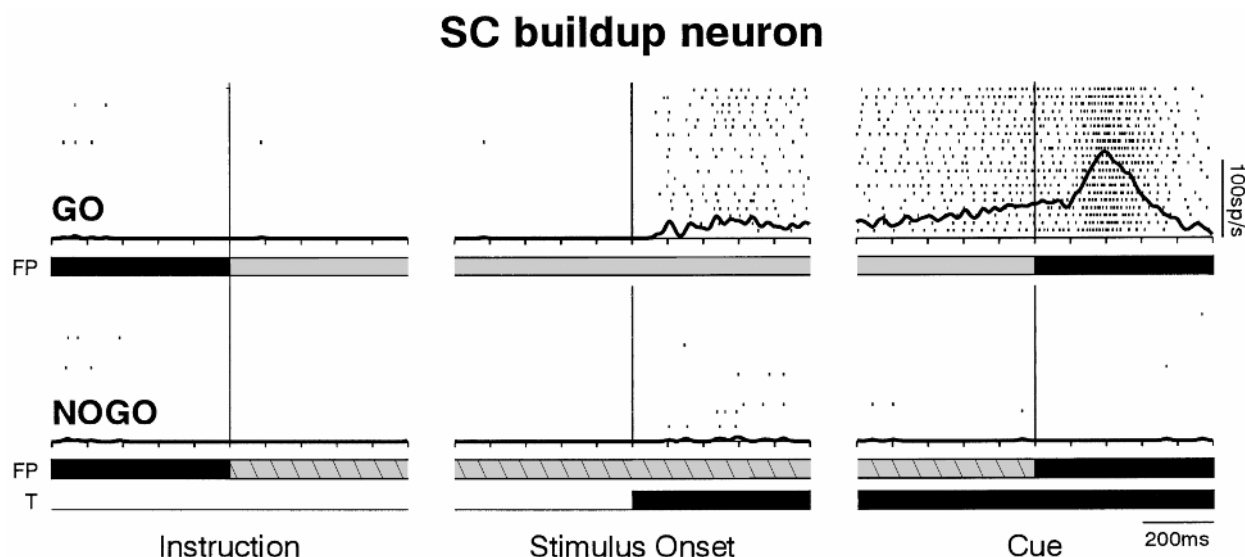

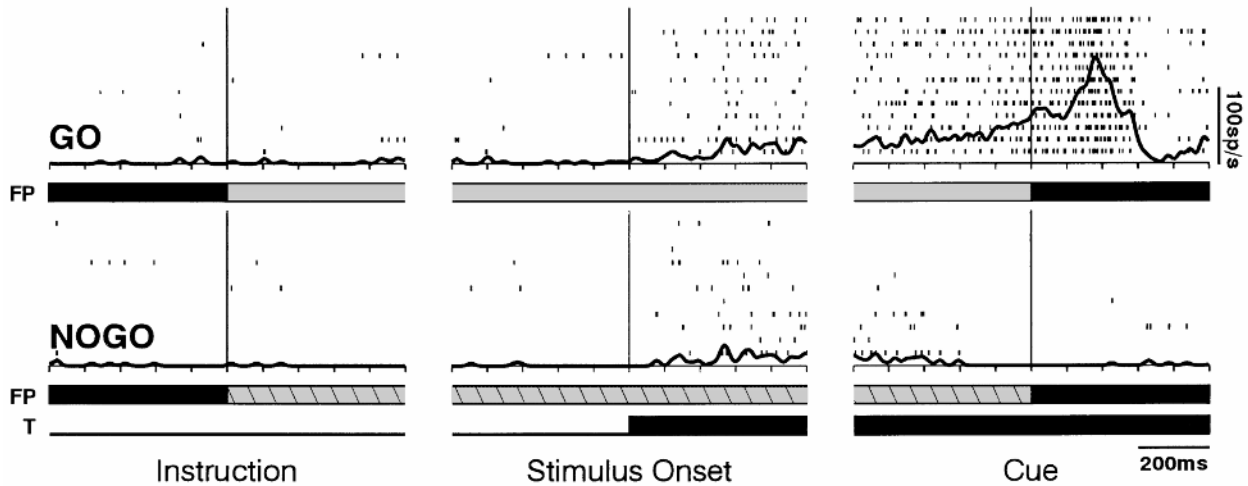

FIGURE 40.8 Neuronal activity of a buildup neuron in a Go/Nogo saccade paradigm. Instructions were given by a change in color of the fixation stimulus (FP) before the peripheral stimulus (T) appeared. A change from blue to red indicated a Nogo instruction, whereas a change to green indicated a Go instruction. After the peripheral stimulus was presented, there was a delay period. After this, the fixation stimulus returned to its original blue color, cueing the monkey to either maintain fixation for a prolonged duration (Nogo) or execute the saccade (Go). Rasters and spike density functions for Go (top) and

Nogo (bottom) trials are aligned on the instruction (left), target (middle), and cue (right). This neuron started to discharge after the target appearance and exhibited delay activity only if the Go instruction had been given. The discharge peaked at the onset of the saccades made in response to the cue presentation. This neuron was virtually silent during Nogo trials. To quantify the level of delay activity, the discharge rate was measured during a 300-ms epoch ending at the time of the cue presentation. This neuron's delay activity was 33.3 sp/s and 0.2 sp/s in Go and Nogo trials, respectively.

A LIP efferent neuron

B FEF efferent neuron

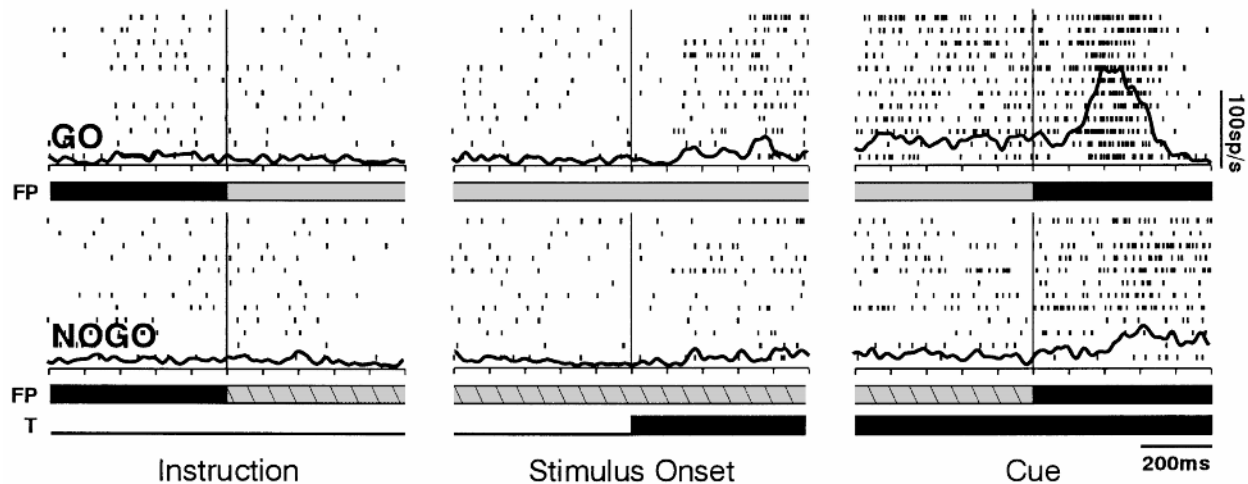

FIGURE 40.9 Neuronal activity of cortical efferent neurons in a Go/Nogo delayed saccade paradigm. Responses of lateral intraparietal (LIP) (top) and frontal eye field (FEF) (bottom) neurons that were activated antidromically by SC stimulation. In the Go trials, the neurons started discharging after the stimulus

onset and maintained their discharge until the saccade was made in response to the cue. In the Nogo trials, less response was observed after the stimulus presentation. Same organization as in figure 40.8.

delay activity in Go trials was only 1.3 times greater than that in the Nogo trials. The delay activity of the LIP neurons started at the time of the visual target and continued for most neurons regardless of whether there was preparation to make the saccade. This is in contrast to the SC neurons, where activity in approximately two thirds of the SC neurons had activity only after the Go instruction, and across the sample there was 2.4 times greater activity on the Go trials. Thus, the SC neurons were substantially more related to the signal to move, and using our inter-

pretation of the Go/Nogo task, were more closely related to the preparation to move whereas the LIP neurons were more dependent on the visual stimulus than the signal to make a saccade.

FRONTAL CORTEX INPUTS TO SUPERIOR COLLICULUS The FEF is the area in the frontal lobe that, together with the SC, is necessary for saccade generation (Schiller, True, and Conway, 1980). Segraves and Goldberg (1987) previously reported that FEF neurons that

are antidromically activated by SC stimulation carry a saccade-related burst signal that sometimes is combined with a response to visual stimulation. We have confirmed this observation and find that approximately 15% of the FEF neurons have only presaccadic bursts. Thus, in contrast to the LIP area, the FEF does have neurons projecting to the SC that have characteristics of the SC burst neurons. As was the case with the LIP region, the FEF projection to SC was topographically organized and directed to the intermediate layers.

In addition to these burst-like neurons, approximately one third of the FEF efferent neurons showed delay activity between the onset of the stimulus and the saccade, which made them similar to the SC buildup neurons. Like the SC buildup neurons, but in contrast to the LIP efferent neurons, nearly two thirds of the FEF efferent neurons with delay activity had activity in Go trials that was higher than in Nogo trials (figure 40.9B). This activity on the Go trials, although frequent, was small, only 1.5 times greater than that observed on Nogo trials (Wurtz and Sommer, 1998). Thus, although the FEF has buildup-like activity as frequently as do the SC neurons, the Go/Nogo effect is smaller, like that in the LIP. The FEF appears to be a more heterogeneous area than is the LIP region and includes both burst- and buildup-type neurons.

While investigating the frontal cortex inputs to the SC, there was an additional finding that raises questions about the unidirectional flow of information from cortex to brainstem outlined in figure 40.2A: electrical stimulation of the SC (Sommer and Wurtz, 1998) showed that many FEF neurons *receive* inputs from the SC, presumably by means of a thalamic synapse (Lynch, Hoover, and Strick, 1994). These FEF neurons always had a phasic visual response, and some also carried signals such as delay activity, a presaccadic burst, or fixation activity. These results suggest that the processes underlying saccade generation involve a bidirectional communication between the SC and cortical areas.

COMPARISON OF SUPERIOR COLLICULUS INPUTS
The neurons in the LIP area and the FEF that project directly to the SC carry an amalgam of visual, delay, and saccade signals, although the ratio of these signals differs between the two areas. The efferents from the LIP area have not been found to show activity comparable to the burst neurons in the SC, whereas FEF efferents frequently do. The efferents of both the LIP area and the FEF show delay activity, but in the LIP area the activity is more pronounced. Thus, the delay activity is represented more heavily in LIP efferents than is the burst, and for the FEF, it is approximately

FIGURE 40.10 Summary of the overlap of activity between neurons in the cerebral cortex (LIP and FEF) that project to the SC and the neurons in the SC (burst and buildup). Activity in the delay period is represented by the horizontal line: the greater the activity, the longer the line. The burst is represented by the height of the vertical bar, the higher the bar the larger the burst. The delay activity is consistently present in LIP and SC buildup neurons, but there is little if any burst in the LIP neurons. The delay activity is also present in the FEF neurons, but these neurons also frequently have a burst of activity, as do the SC burst neurons. There are therefore both *differences* between the neurons in the two cortical areas projecting to the SC and *overlap* between the cortical activity and SC activity, the LIP having greater similarity to the SC buildup neurons than to the SC burst neurons and the FEF tending to have the reverse relationship.

the reverse. Figure 40.10 compares schematically this overlap of the activity in the LIP efferents, the FEF efferents, and the SC buildup and burst neurons. Whether this input is directed separately to the burst and buildup neurons in the SC remains to be determined. Because signals also are transmitted from the SC to cortex (and between the FEF and the LIP area as well), the development of saccade-related activity must result from the continuous interaction between multiple brain structures, including the FEF, the LIP area, and the SC.

CONCLUSION: DISTRIBUTED PROCESSING The shifts in processing from one area to the next in the brain logically could be of substantially different types (Miller, 1988). On the one hand, this processing could be discrete: the processing in one area is completed and the result is passed on to the next area, where a new stage of processing begins. Conversely, the processing might be distributed: the same type of processing in one area continues at some higher level in the next area. Comparison of the activity of cortical and SC neurons offers one of the few opportunities in sensorimotor systems to determine which type of transformation occurs. In the visual-oculomotor processing that we have considered, it is distributed processing. One of our most striking observations is that the same type of neuronal activity can be identified in both the cortex and

the SC and that there is simply a shift in the characteristics of the processing. For example, the processing conveyed by buildup neurons is carried on in both the parietal cortex and the SC, but analysis of the nature of the continuing activity shows that there is a shift in the dependence of that activity toward the preparation to make a saccade.

41 The Neural Correlates of Place and Direction

M. A. WILSON

ABSTRACT Recent findings have shed new light on the biological mechanisms underlying our sense of direction and place. Distinct brain subsystems in the hippocampus, thalamus, subicular, and parietal regions display direct neural correlates of head orientation and spatial location within specific environments. The behavior of cells in these areas also is affected strongly by prior experience, suggesting a significant mnemonic component to these systems. The trajectory dependence of activity within the hippocampus suggests a role in processing of route or ordered mnemonic information.

Navigation and maps

Navigation can be defined simply as the process of getting from place to place. Although simple to describe, its successful execution can be quite complex. This problem can be solved through a calculation of a trajectory between locations using the determinations of position, course, and distance traveled. Such traversal can involve establishing an initial position and bearing and then updating this information by keeping track of self-movement in a process known as “dead reckoning.” Taken in this sense, we see that navigation is fundamentally a process of map traversal and without doubt, many animals are quite adept at carrying out such navigational feats (Gallistel, 1990).

However, the process also can be viewed at another level, one that may strike many as more consonant with their own personal experience. Going from one place to another frequently involves traversing a network of intermediate points—following a route in which familiar landmarks indicate progressive success and dictate new courses of actions. Using such a strategy requires the ability to identify landmarks and to establish spatial orientation with respect to them. This is the navigational strategy not of maps, but of routes. One easily can see how these systems relate to one another. Traversing the

gap between intermediate points of a route can itself become a mapping process.

A distinctive difference between route and map-based navigation is the relaxation of the need for precise metric information, particularly that of distance. This is familiar to those who have viewed a navigational guide to a subway in which distance typically is distorted but nevertheless provides perfectly adequate instruction for achieving the ultimate objective of reaching one place from another. But the two fundamental pieces of information that are shared by both map- and route-based strategy are those of place and heading.

In 1978, O’Keefe and Nadel outlined several basic systems for rodent spatial navigation. Routes and cues were maintained by a *taxon* system, whereas maps were part of the *locale* system. The hippocampus in particular was implicated as the heart of the locale system, the site of the cognitive map. But recently, many other areas involved in the evaluation of distance, location, and directions have been identified. These areas also have been found to contribute to other forms of spatial behavior, such as visual search and reaching, suggesting related features of motor control.

In this chapter, we examine in detail the neural systems that appear to be involved in establishing and maintaining a sense of place and direction.

Our ability to recall childhood memories is limited to those events occurring roughly after the age of 3 years that overlap with the emergence of more mature spatial navigational strategies (Hermer and Spelke, 1996). Thus begins the relationship between our sense of place and our ability to form lasting memories of events, linked through the hippocampus, a brain structure that lies at this intersection of memory and spatial cognition. Figure 41.1 diagrams the pathways that lead to the hippocampus. These include structures in the parietal lobe that have been associated with spatial localization and movement (see chapter 36), areas in the frontal lobe which are responsible for the coordination of actions (see chapter 38), areas in the temporal lobe

involved in object identification, and thalamic areas carrying directional information.

A SENSE OF PLACE *Perirhinal, postrhinal, and entorhinal cortex* Identification and localization of landmarks are important for establishing position and bearing during

navigation. In rodents, this landmark information appears to pass through perirhinal and postrhinal cortices that lie along the rhinal sulcus of the temporal lobe. The perirhinal cortex receives significant input from sensory areas that may code for stimulus attributes such as somatosensory, auditory, and olfactory cortices. The postrhi-

Place

FIGURE 41.2 The systems involved in carrying place information.

nal cortex (corresponding to primate parahippocampal cortex [Burwell, Witter, and Amaral, 1995]) receives input from visual and spatial areas, such as posterior parietal cortex, that may carry information about stimulus location, angle, and distance. The outputs of these structures converge in the entorhinal cortex, where the integration of spatial and attribute information may occur (figure 41.2) (Burwell and Amaral, 1998). Behavioral studies in rodents (Bunsey and Eichenbaum, 1993; Wiig, Cooper, and Bear, 1996; Mumby and Pinel, 1994; Zhu, Brown, and Aggleton, 1995) and in primates (Suzuki et al., 1993; Gaffan and Murray, 1992; Murray and Mishkin, 1986; Zola-Morgan et al., 1989) demonstrate the importance of these structures in spatial and object memory tasks. Human imaging studies have shown that these areas are active during navigation (Aguirre et al., 1996) and viewing of spatial scenes (Epstein and Kanwisher, 1998). Interestingly, combined lesions of perirhinal and postrhinal cortex impair object recognition but still allow rodents to perform some spatial memory tasks, showing that spatial navigation is not entirely de-

pendent on landmark recognition (Aggleton et al., 1997).

The hippocampus The hippocampus is a brain region that has been implicated in the formation and long-term consolidation of episodic memory (Zola-Morgan and Squire, 1993; Scoville and Milner, 1957). It receives convergent information from unimodal and multimodal association cortices through the entorhinal cortex (figure 41.1). Damage to the hippocampus leads to severe spatial learning deficits in animals (O'Keefe and Nadel 1978), and recent functional imaging studies have related hippocampal activation with spatial navigation and memory in humans (Maguire, Frackowiak, and Frith, 1997; Maguire et al., 1998; Ghaem et al., 1997).

Place cells Hippocampal pyramidal cells recorded in freely behaving rodents have spatial receptive fields that are restricted to relatively small regions (5%–30%) of specific environments. Different cells are active in different locations, and the region of space in which they are active is referred to as the “place field” of the cell (O'Keefe and Dostrovsky, 1971). Individual cells can show remarkably consistent firing patterns over long periods of time, with repeated placement in the same environment, and cells will have different place fields in different environments (Thompson and Best, 1989; Kubie and Ranck, 1983; O'Keefe and Speakman, 1987). Ensembles of 50 to 100 cells can convey sufficient information over a 1-second interval to precisely locate an animal in space to within a few centimeters, and in any given environment, 30% to 50% of all hippocampal pyramidal cells may have fields (Wilson and McNaughton, 1993) (figure 41.3; see color plate 25). Place cells have been identified in all CA regions of the hippocampus and dentate gyrus (Jung and McNaughton, 1993) and in the subiculum (Sharp and Green, 1994), superficial layers of the entorhinal cortex (Quirk et al., 1992) and parasubiculum (Taube, 1995a). Place cells typically require active locomotion through the field for spatial firing but respond to passive movement of the animal through its place field under certain conditions. Animals moved through their place fields under conditions of severe restraint show an absence of spatially related firing (Foster, Castro, and McNaughton, 1989). This is related to the significant influence of behavioral state on hippocampal activity. Pyramidal cells recorded while an animal is resting quietly or sleeping lose both their characteristic 8- to 10-Hz rhythmic activity and spatial selectivity. Although place fields persist after removal of individual visual cues (O'Keefe and Speakman, 1987), as well as in total darkness (Markus et al., 1994; Quirk, Muller, and Kubie, 1990), rotation of individual cues results in corresponding rotation of place fields,

FIGURE 41.3 Spatial firing distributions of 144 hippocampal place cells recorded simultaneously while the rat explored a 60×45 -cm apparatus. Each panel represents the firing distribution of one cell. Red indicates high firing, dark blue indicates no firing. The 7 high rate cells are inhibitory interneurons, the

rest are pyramidal cells. The spatial encoding by hippocampal cells is sufficiently robust that the animal's location in the apparatus can be predicted to within a few centimeters solely on the basis of the mean firing rate distributions and the activity of these cells over a 1-second window.

indicating that visual cues can exert strong influence over spatial firing but can be supplanted by nonvisual, presumably idiothetic information, under certain conditions.

Although place cells can show spatial specificity on the first exposure to a spatial location (Hill, 1978), the robustness of response improves significantly with repeated exposures over the course of 5 to 10 minutes. The coordinated activity of ensembles of neurons also was found to vary as a result of experience (Wilson and McNaughton, 1993). This finding suggests that familiarity may be reflected in the degree of coordinated activation of hippocampal ensembles, which itself may be a function of activity dependent synaptic plasticity.

In a related finding, McHugh and associates (1996) examined the spatial firing characteristics of hippocampal CA1 cells in mice with CA1-specific genetic deletion of *N*-methyl-D-aspartate (NMDA) receptors. This deletion effectively eliminated NMDA-dependent long-term potentiation (LTP), a primary form of activity dependent on synaptic plasticity in this region. Although these animals still showed place-related firing, the fields themselves were larger and more variable, and ensembles of cells with overlapping place fields showed no significant covariation, in a sense never making the transition from novel to familiar firing patterns due to the absence of synaptic plasticity (figure 41.4; see color plate 26).

Although spatial location is a dominant factor influencing the activity of place cells during random foraging, during repeated traversal of a fixed path—such as running back and forth on a linear track—the firing of these cells becomes highly directional. Cells show high rates of firing when the animal is moving through the location of the field in a particular direction and are silent when it moves through the same location in the opposing direction (McNaughton, Barnes, and O'Keefe, 1983).

This directional dependency does not require linear behavior and emerges whenever an animal repeatedly follows a trajectory. Additionally, this directionality is not constrained by fixed heading and can appear during repeated turns of a given orientation or along circular paths that span 180° (Wilson, unpublished observations). Muller and colleagues (1994) have argued that differences in directional selectivity during linear track and open-field behavior demonstrates that directionality is not a fixed attribute of hippocampal place cells but rather is a function of task and environment.

REFERENCE FRAMES For navigational purposes, spatial information must be maintained relative to one or more reference frames. Gothard and associates (1996) recorded multiple simultaneous place cells during a task in which the animal made repeated excursions from a start-

FIGURE 41.4 The effect of blockade of synaptic plasticity on the robustness of the spatial signal in the hippocampus of a mouse. This mouse was engineered genetically to knock out the NMDA receptor selectively in region CA1 (Tsien, Huerta, and Tonegawa, 1996). Trajectory reconstruction is shown for normal and disrupted animals. This also is compared with trajectory reconstruction in normal rats during novel and familiar exposure to an environment. Accurate transmission of spatial information appears to require both experience and synaptic plasticity.

ing box to a goal site, each of which were placed at varied locations in a large environment. They found cells that responded to multiple reference frames as defined by the room, start, and goal boxes. These responses were distributed across largely nonoverlapping populations of cells and were active simultaneously, with some cells responding at fixed locations with respect to the room, and other cells responding as the animal approached or left the start and goal points. These results demonstrate the complex manner in which context must be defined relative to relevant cues.

The reference frames need not be defined purely by spatial or geometric factors. Markus and coworkers (1995) found that different place cells could be activated depending not only on the location and heading of the animals but also based on the task the animal was performing. Rats were trained on an open field either to forage for randomly scattered food pellets or to sequentially visit four locations arranged in a square configuration. Place fields in these two tasks differed, and when the animal was cued to switch between these tasks at

random times, the place cells were able to switch rapidly to the appropriate task-dependent representation.

GEOMETRY AND PLACE Burgess and O'Keefe (1996) demonstrated that geometric distortion of a small enclosure through stretching walls in a way that preserved the basic topology of the space but altered relative distance between points resulted in place cells that were stretched similarly. These cells appeared to preserve the topology or connectedness of adjacent locations at the expense of absolute distance. The loss of distance information with preservation of topological and geometric information points, when combined with the emergence of directional firing during repeated path following, points to a strong influence of route or trajectory information over absolute spatial information. Gallistel (1996) has argued that this geometric information is used for both orientating animals in space as well as localizing goals within that space.

A SENSE OF DIRECTION Our ability to perceive and maintain a sense of direction is tied fundamentally to a subsystem of sensory (primarily visual and vestibular) brain areas. Behavioral studies in animals have demonstrated an ability to establish and maintain a sense of direction (Mittelstaedt and Glasauer, 1991; Gallistel, 1990; Etienne, Maurer, and Seguinot, 1996). Berthoz (1997) points out that although it has been shown that humans are capable of acquiring and reproducing spatial trajectories using the integration of linear and angular vestibular information alone, patients with vestibular deficits still could maintain distance information, but directional information was lost. This suggested that vestibular information contributed to the sense of orientation, whereas motor information contributed to estimates of distance.

By integrating both angular and linear self-motion information along a path relative to a starting point, the simple form of navigation known as "dead reckoning" can be carried out. This system of path integration requires that distance and direction be computed. Insects may accomplish this through monitoring visual flow, counting footfalls, or tracking position of the sun (Gallistel, 1990), whereas rodents may use vestibular and motor efferents in conjunction with visual landmark evaluation. The use of this system typically is demonstrated by assessing the ability of an animal to take a meandering outward path from a starting point to a goal and then return along a straight line following the shortest path to the start (Etienne, Maurer, and Seguinot, 1996). Whishaw and Maaswinkel (1998) have argued that the ability to carry out this navigational task in the absence of visual guidance requires intact hippocampal

function. McNaughton and associates (1996) have proposed a model that identifies the hippocampus as a system that is preconfigured to support dead reckoning.

Head direction cells Maintaining orientation, or heading, is a process of establishing a stable angular reference with respect to a particular reference frame in which one wishes to carry out navigational behavior. The relationship between points within these reference frames, such as distance and direction, defines coordinate systems. These reference frames may exist "out there" in the world, independent of the organism. In such "allocentric" reference frames, coordinates are independent of the orientation of the body in space (Tolman, 1948; O'Keefe and Nadel, 1978). Allocentric coordinates are not necessarily of a fixed scale and could encompass a single room, a building, or an entire city. As these examples suggest, they also may be nested and dependent on one another.

Egocentric reference frames are those that are relative to the organism. They may define a space relative to the head, the eye, or the hand, and once again we see that movement through this space relative to the body becomes a matter of traversing multiple, nested frames of reference. Although we largely confine our discussion to issues of allocentric localization and orientation, in chapters 36 and 38, we see similar issues arise in the context of motor control of reaching and gaze.

Although allocentric coordinate systems appear to be defined exclusively by the measured relationships between objects in the world, an organism could use a separate self-constructed coordinate system within that external space. In particular, idiothetic information—those signals generated by the actions of the organism itself—can serve to construct such a self-contained reference system through the process of path integration, allowing an actions to be carried out in the absence of or in the face of unreliable information from the external world. The most familiar of these internal signals are those arising from the vestibular and proprioceptive systems.

Significant progress has been made in identifying both the regions and the factors that influence these directional signals. Head direction cells have been identified in a number of regions of the brain, including the anterior dorsal nucleus of the thalamus (ATN) (Taube, 1995b), the lateral dorsal thalamic nucleus (LDN) (Mizumori and Williams, 1993), the striatum (Wiener, 1993), the retrosplenial or posterior cingulate cortex (Chen et al., 1994), and postsubiculum (PoS) (Taube, Muller, and Ranck, 1990). These regions maintain a precise representation of current heading with narrow tuning characteristics. These head direction cells fire

independently of the animal's location within an environment with preferred firing directions distributed over 360°. Although cells in each of these regions respond with similar directional specificity, they do show different sensitivity to visual, vestibular, and motor efferent signals (reviewed in Taube et al., 1996).

Parietal, retrosplenial, striatal head direction cells Only a small fraction of cells in the parietal cortex have been reported to show directional firing (<5%) and therefore are unlikely to represent a significant source of directional information. Head direction cells in the retrosplenial cortex share a number of attributes with the thalamic and PoS cells but show greater variability of response and broader tuning curves and lower frequency of occurrence (<10%) (Chen et al., 1994). These systems probably derive directional information from multiple convergent sources and therefore reflect a higher-order evaluation of direction. Cells with head directional correlates in the striatum are small in number (<10%), with additional behavioral correlates such as spatial preference and task sensitivity. These cells also are unlikely to serve as the basis for a basic directional system and are more likely to relate to task and behavioral elements that have directional attributes. This may be similar to the type of directionality seen in hippocampal cells during repeated path traversal.

In rodents, lesions to the parietal cortex produce long-lasting deficits in tasks that require learning object/spatial relationships but leave object recognition unaffected (Decoteau and Kesner, 1998). Interestingly, such lesions do not seem to impair allocentric distance estimates (Long and Kesner, 1996), suggesting that orientation may be particularly dependent on intact parietal function. Retrosplenial lesions also fail to impair several tasks involving memory for spatial location (Neave et al., 1994) or object identity (Ennaceur, Neave, and Aggleton, 1997). Similarly, in humans, lesions in the retrosplenial and parietal regions produce deficits in memory for directional orientation between objects while leaving the ability to identify those objects intact (Takahashi et al., 1997).

Anterior, lateral dorsal thalamic nuclei, and the postsubiculum The most prominent directional signals arise from thalamic and postsubicular regions. Mizumori and Williams (1993) found that LDN cells required visual input to establish their initial directional specificity but could maintain responsiveness in the absence of visual cues. Additionally, maximal directional firing for individual cells was established after exposure to multiple cues at different headings and locations rather than single cues in the preferred direction, suggesting a contextual as well as perceptual influence on the directional signal.

They also identified a correlation between directional specificity and errors on the radial arm maze.

Dudchenko and Taube (1997) found a similar relationship between head direction cells and errors on a spatial reference memory task. They also reported an absence of goal related modulation of head directional activity.

Taube (1995b) identified a difference between postsubicular (PoS) and anterior thalamic head (ATN) direction cells. PoS cells maintained directional firing during passive rotation of a restrained animal whereas cells in the ATN did not, suggesting that ATN cells require volitional movement signals.

The ability of visual cues to override internal signals was examined by Goodridge and Taube (1995). Animals were presented with conflicting directional information from internal directional sources (e.g., self-motion and vestibular integration) and external sources (visual cues) by reintroducing a familiar landmark at a position that was inconsistent with current directional firing. Cells in both the ATN and PoS shifted their firing to match the direction indicated by prior experience with the landmark.

Interestingly, Taube and Burton (1995) report that these cells can change preferred direction when an animal moves from one environment to the next, suggesting that this directional system is tied to individual frames of reference rather than serving as an absolute measure of heading. They also discovered that repeated conflict between visual and idiothetic cues led to a reduction in the control of visual cues over directional response.

In a related study, Knierim and associates (1995) examined the influence of familiar and salient visual cues on thalamic head direction cells and place cells in the hippocampus (CA1 and CA3) when the relationship between internal and external directional signals was placed repeatedly in conflict through disorientation (repeated rotation in a closed container). Animals were trained to forage for randomly scattered food pellets in a circular gray environment with a single salient visual cue (a white or black cue card covering 90° of the cylinder wall). Under these conditions, the cue card had minimal influence on reorienting the animals' directional and place responses. This disruption of cue-control was evident even in animals that were not subjected immediately to the disorientation procedure but that had been through the experience weeks before testing. These results point to the importance of the animal's perception of cue stability as a factor in predicting the degree of influence the cue has on directional and spatial orientation. After such disorientation, the variation in directional and place firing remains strongly coupled, suggesting that disorientation relates more

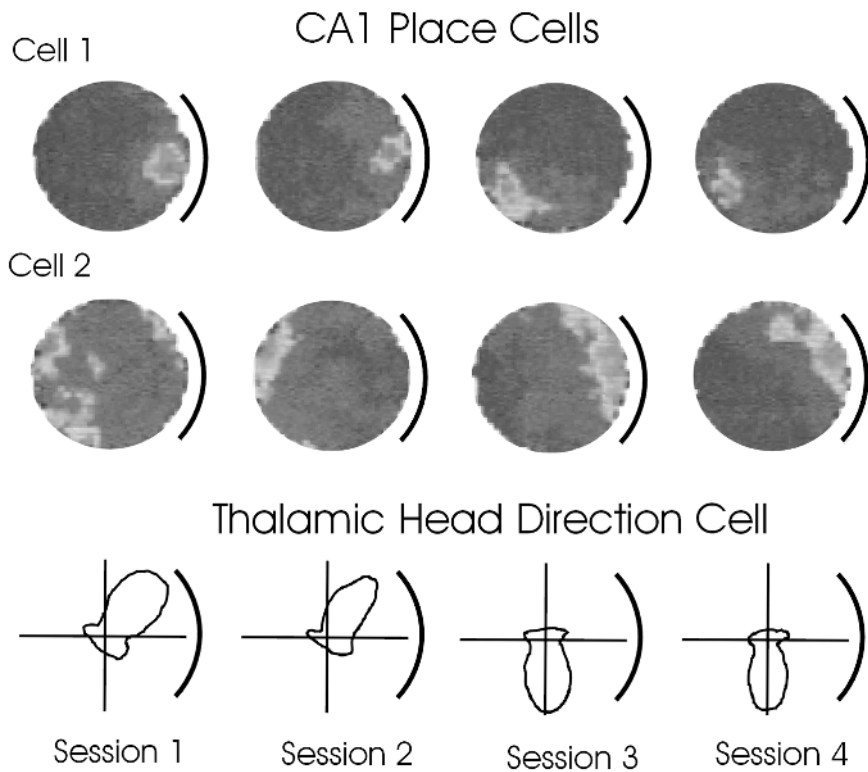

FIGURE 41.5 Spontaneous rotation of hippocampal place cells and thalamic directional cells after disorientation.

directly to reference frame orientation than consistency of place or positional information (figure 41.5; see color plate 27). This study also offered some insight into the parameters that may govern the balance between visual versus internal directional cues. Rotation of the cue cards by less than 45° was more likely to produce a correction of head direction cells. This suggests that passively maintained internal heading information may have significant intrinsic error that must be updated frequently to maintain integrity. This is consistent with the observation that place and directional firing in hippocampal and surrounding regions degrades over 5- to 10-minute periods of open-field exploration in the dark, and that the interval can be reduced significantly through further elimination of nonvisual intramaze cues.

Dudchenko, Goodridge, and Taube (1997) found that animals that were impaired in a radial arm maze task after disorientation still followed single distal landmarks. These results suggest that learned association between a landmark and stable experience is not required for a landmark to influence head direction responses. It also suggests that disorientation can influence not only the variability of the directional signal but that the use of the signal in guiding behavioral responses. A similar dissoci-

ation was proposed to exist between spatial firing of hippocampal cells reflecting response specificity and the covariance of place-cell ensembles, reflecting response familiarity or reliability (McHugh et al., 1996).

Although visual cues have been found to exert a variable influence on directional firing, removal of self-motion cues through vestibular system lesions were found to completely abolish directional firing of ATN cells, with only minor impact on locomotive behavior but significant impact on navigational ability (Stackman and Taube, 1997).

Conversely, lesions of the hippocampus had no impact on directional firing of cells in either the postsubiculum or the ATN (Golob and Taube, 1997). In addition, the preferred firing direction of these cells remained stable over several days of repeated exposure to an environment. This suggests that the contextual information required for establishing orientation within an environment may be more limited than the information provided by the hippocampus for establishing spatial location or context. In a complementary manner, Smith (1997) reviewed studies that suggest that hippocampal function may be capable of compensation for the orientation deficits introduced by vestibular dysfunction. These results reinforce the notion that the sense of direc-

tion and the sense of place are separate faculties maintained by distinct brain structures.

CONNECTIVITY BETWEEN DIRECTIONAL SUBSYSTEMS
Anatomic studies have identified reciprocal connectivity between many of the regions with head directional cells (figure 41.6). To identify the dependencies between some of these structures, Goodridge and Taube (1997) performed lesions of either the ATN or the PoS and recorded from head direction cells in the remaining structure. They found that ATN cells maintained directional firing after PoS lesions, but that lesions of the ATN abolished directional firing in the PoS. Examination of the directional responses in ATN cells with the PoS removed revealed a reduction in visual cue control and broader directional tuning. These results suggest that the PoS contributes information needed for visual control of orientation, but consistent with earlier results indicating the variable influence of visual cues on directional firing, elimination of this information through PoS lesions did not abolish directional response. Conversely, disruption of ATN lesions, like vestibular system lesions, led to complete disruption of directional response, again pointing to the critical role of vestibular information in orientation.

Lesions of the LDN, which is connected reciprocally with the PoS (Golob, Wolk, and Taube, 1998), did not affect directional firing of PoS head direction cells and did not affect visual cue control.

Two studies have suggested that the firing of ATN cells is correlated more closely with the animal's future head direction (20–30 msec) whereas PoS activity corresponds to current heading (Taube and Muller, 1998; Blair and Sharp, 1996). This effect may result from differential contributions of motor efferent copy signals to the ATN and the PoS or from delay associated with the ATN to PoS-directed drive revealed in earlier lesion studies. Direct motor drive of ATN cells with minimal delay is consistent with earlier discussion of ATN disruption during passive rotation, although continued firing of PoS cells under these conditions indicates a more complex pattern of interaction.

The retrosplenial cortex lies at the convergence of neocortical sensory, thalamic directional, and hippocampal spatial systems. This would provide a convenient site for the integration of distal information, whereas the convergence of self-motion (idiothetic) information, place, and direction in the pre-, post-, and parasubicular areas would provide a convenient site for path integration. The close relationship of retrosplenial and subicular cortices would allow for interaction between distal and idiothetic systems, enabling visual updating of directional sense as well as vestibular correction for egocentric object coordinates.

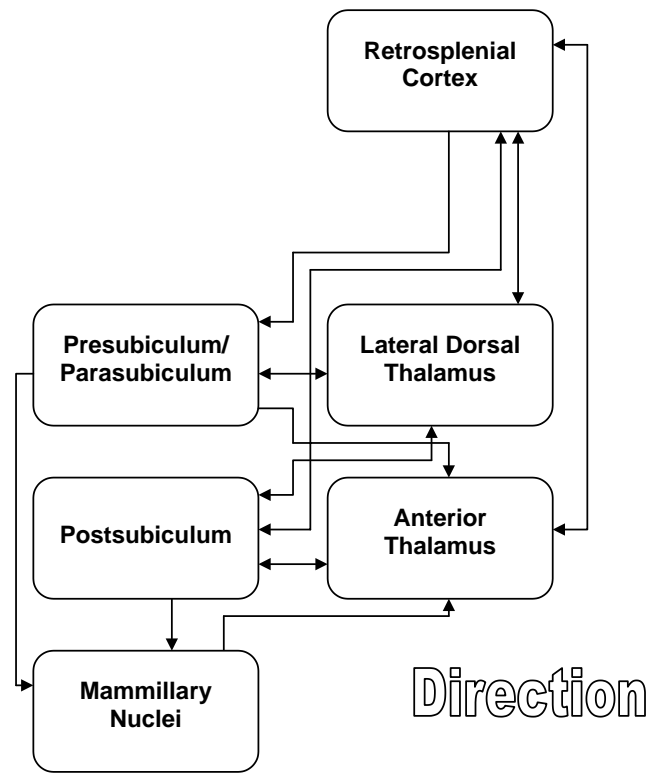

FIGURE 41.6 The systems involved in carrying directional information.

Computational models

Based on many of the findings described, a number of models have been proposed that combine these systems into a comprehensive neural architecture for navigation (see Trullier et al., 1997, for a review).

Brown and Sharp (1995) describe a model of navigation that uses a stimulus-response strategy for route learning. In this model, head direction and place cells activate “motor” cells. The resulting change in position and heading after motor response activates a different set of place and head direction cells, leading to the next response. This approach is similar to the “local view” hypothesis proposed by McNaughton, Chen, and Markus (1991). Although this simple S-R model allows rapid route learning, it does not lend itself well to novel route generation.

Redish and Touretzky (Touretzky and Redish, 1996; Redish and Touretzky, 1997) offer a comprehensive model of navigation based on anatomic segregation and connectivity of structures in the hippocampus, the thalamus, and the neocortex. They divide the problem of navigation into six distinct subproblems—local view, head direction, path integration, place coding, goals, and reference frames.

Foster and associates (1998) describe a computation model of navigation that combines mechanisms of dead reckoning and reward learning with an internal representation of allocentric space to provide a framework for rapid learning of trajectories to goals. Learning in the model is based on the well-established temporal difference rule, and the hippocampus provides crucial map information for optimizing trajectories based on spatial adjacency of paths. The model is particularly interesting because it is able to solve not only a conventional spatial reference memory task in the Morris water maze but also a novel and computationally difficult delay match to place task.

RELATION TO OTHER MOTOR CORTICAL CONTROL SYSTEMS The process of navigation bears similarities to other motor control problems. These include the controlled movement of the eyes during visual exploration of a scene and movement of the limbs during spatial exploration, or reaching for objects in space. Each of these tasks requires the identification of target objects, evaluation of their spatial location within a sensory coordinate system, transformation of that spatial information into a motor output coordinate system, initiation of action based on the target and its location, and maintenance or integration of changes in spatial information resulting from those actions. In chapter 38, Rizzolatti and colleagues describe neurons in the primate premotor area that contain a “vocabulary” of motor actions that can be modulated by activity in parietal cortical areas. In chapter 36, Andersen and associates describe neurons in the posterior parietal cortex that provide the sensory context for execution of planned eye and arm movements. There also is evidence that the hippocampus may be involved in sequences of visually guided memory saccades (Müri et al., 1994).

Summary

Directional and place information is maintained by distinct hippocampal, subicular, and thalamic subsystems that are capable of incorporating intrinsic self-motion signals and extrinsic cue information in a stable representation of orientation and location. These signals also are highly dependent on prior experience, demonstrating their dependence on memory. Cells in the hippocampus that are modulated strongly by spatial location also show strong trajectory dependence, which suggests a role of this system in route- or order-related mnemonic and navigational processing. These systems can be related to more general motor control systems that involve the planning and guidance of actions in space.

42 Computational Motor Control

MICHAEL I. JORDAN AND DANIEL M. WOLPERT

ABSTRACT The authors discuss some of the computational approaches that have been developed in the area of motor control. They focus on problems relating to motor planning, internal models, state estimation, motor learning, and modularity. The aim of the chapter is to demonstrate, both at a conceptual level and through consideration of specific models, how computational approaches shed light on problems in the control of movement.

The study of motor control is fundamentally the study of sensorimotor transformations. For the motor control system to move its effectors to apply forces on objects in the world or to position its sensors with respect to objects in the world, it must coordinate a variety of forms of sensory and motor data. These data generally are in different formats and may refer to the same entities but in different coordinate systems. Transformations between these coordinate systems allow motor and sensory data to be related, closing the sensorimotor loop.

Equally fundamental is the fact that the motor control system operates with dynamic systems whose behavior depends on the way that energy is stored and transformed. The study of motor control, therefore, also is the study of dynamics. These two interrelated issues—sensorimotor transformations and dynamics—underlie much of the research in the area of motor control.

From a computational perspective, the motor system can be considered a system whose inputs are the motor commands emanating from the controller within the central nervous system (CNS) (figure 42.1, center). To determine the behavior of the system in response to this input, an additional set of variables, called *state variables*, also must be known. For example, in a robotic model of the arm, the motor command would represent the torques generated around the joints and the state variables would be the joint angles and angular velocities. Taken together, the inputs and the state variables are sufficient to determine the future behavior of the system. It is unrealistic, however, to assume that the controller in the CNS has direct access to the state of the system that

it is controlling; rather, we generally assume that the controller has access to a sensory feedback signal that is a function of the state. This signal is treated as the output of the abstract computational system.

In this chapter, we consider five issues that arise in considering the general computational schema in figure 42.1. The first issue is that of motor planning, which we consider to be the computational process by which the desired outputs of the system are specified, given an extrinsic task goal. Second, we explore the notion of internal models, which are systems that mimic—within the CNS—the behavior of the controlled system. Such models have a variety of roles in motor control that we elucidate. Third, we consider the problem of state estimation, which is the process by which the unknown state of the motor system can be estimated by monitoring both its inputs and its outputs. This process requires the CNS to integrate its internal state estimates, obtained via an internal model, with the sensory feedback. We then consider how internal models are refined through motor learning. Finally, we discuss how multiple internal models can be used in motor control.

Although many of the concepts discussed are applicable to all areas of motor control, including eye movements, speech production, and posture, we focus on arm movements as an illustrative system.

Motor planning

The computational problem of motor planning arises from a fundamental property of the motor system: the reduction in the degrees of freedom from neural commands through muscle activation to movement kinematics (Bernstein, 1967) (figure 42.2). Even for the simplest of tasks, such as moving the hand to a target location, there are an infinite number of possible paths that the hand could move along, and for each of these paths, there are an infinite number of velocity profiles (trajectories) the hand could follow. Having specified the hand path and velocity, each location of the hand along the path can be achieved by multiple combinations of joint angles, and, due to the overlapping actions of muscles and the ability to co-contract, each arm configuration can be achieved by many different muscle activations. Motor planning can be considered as the computational

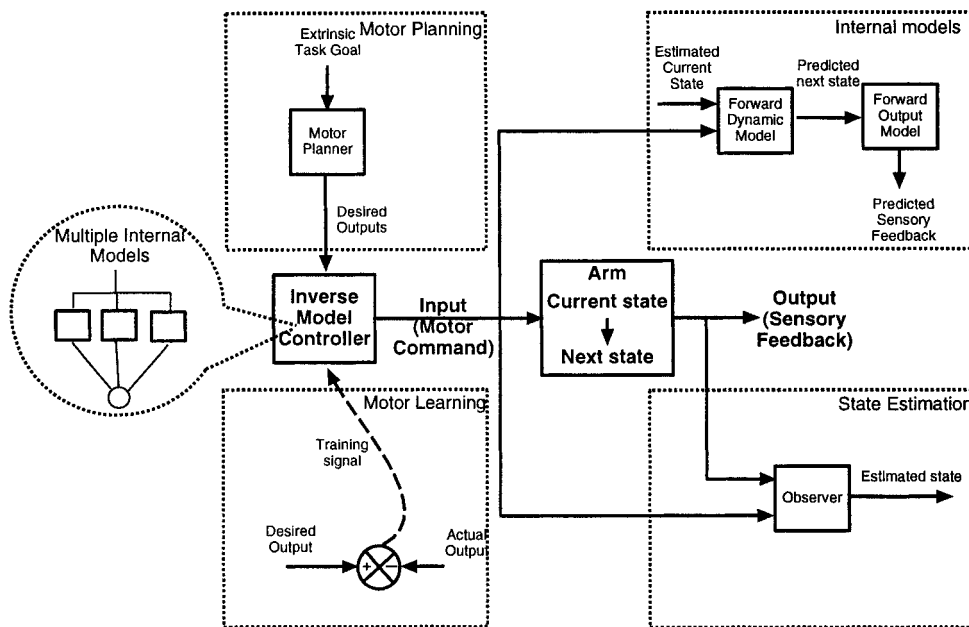

FIGURE 42.1 The motor system is shown schematically, along with the five themes of motor control reviewed in the chapter. The motor system (center) has inputs—the motor commands—

which causes it to change its states and produce an output—the sensory feedback. For clarity, not all lines are shown.

process of selecting a single solution or pattern of behavior at the levels in the motor hierarchy (figure 42.2), from the many alternatives that are consistent with the task.

Given the redundancy in the motor system, it is illuminating that experimental observations of unconstrained point-to-point reaching movements have demonstrated that several aspects of movements tend to remain invariant, despite variations in movement direction, movement speed, and movement location (Morasso, 1981; Flash and Hogan, 1985). First, as shown in figure 42.3a, the motion of the hand tends to follow roughly a straight line in space. This observation is not uniformly true; significant curvature is observed for certain movements, particularly horizontal movements and movements near the boundaries of the workspace (Atkeson and Hollerbach, 1985; Soechting and Lacquaniti, 1981; Uno, Kawato, and Suzuki, 1989). The tendency to make straight-line movements, however, characterizes a reasonably large class of movements and is somewhat surprising given that the muscles act in rotating coordinate systems attached to the joints. Second, the movement of the hand is smooth. Higher derivatives of the hand motion, such as the velocity and acceleration, tend to vary smoothly in time. Consider the plot of tangential speed shown in figure 42.3b. Scrutiny of the curve in the early phase of the motion reveals that the slope of the plot of speed against time is initially zero and increases smoothly. This is striking, given that the positional error is maximal at the beginning of the movement. Third, the

shape of the plot of hand speed is unimodal and roughly symmetric (bell-shaped). There are exceptions to this observation as well, particularly for movements in

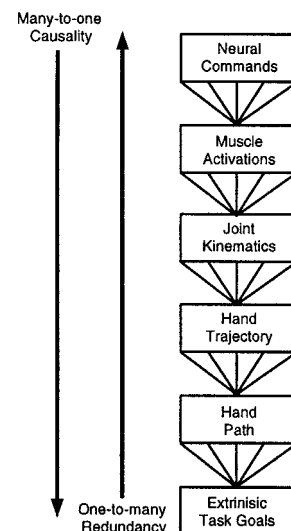

FIGURE 42.2 The levels in the motor hierarchy are shown, with the triangles between the levels indicating the reduction in the degrees of freedom between the higher and lower levels. Specifying a pattern of behavior at any level completely specifies the patterns at the level below (many-to-one: many patterns at the higher level correspond to one pattern at the lower) but is consistent with many patterns at the level above (one-to-many). Planning can be considered as the process by which particular patterns, consistent with the extrinsic task goals, are selected at each level. Reprinted with permission from Wolpert (1997).

which the accuracy requirement leads to feedback playing an important role (Beggs and Howarth, 1972; MacKenzie et al., 1987; Milner and Ijaz, 1990), but again this observation characterizes a reasonably large class of movements.

OPTIMAL CONTROL APPROACHES Optimization theory provides a computational framework that is natural for a selection process such as motor planning (Bryson and Ho, 1975). Rather than describing the kinematics of a movement directly, in terms of the time-varying values of positions or angles, the movement is described more abstractly, in terms of a global measure, such as total efficiency, smoothness, accuracy, or duration. This global measure encodes the cost of the movement, and the optimal movement is the movement that minimizes the cost. In this framework, the cost function is a mathematical means for specifying the plan. The variables that determine the cost, and that are therefore planned, determine the patterns of behavior observed. For example, we might postulate that the trajectory followed by the hand is the one that minimizes the total energy expended during the movement. The theoretical goal is to formulate a single such postulate, or a small set of postulates, that accounts for a wide variety of the data on reaching.

Let us begin by considering the mathematical machinery that is needed to describe “optimal” movements. Letting T denote the duration of a movement and letting $x(t)$ denote the value of degree of freedom x at time t , a movement is a *function* $x(t)$, $t \in [0, T]$. There are an infinite number of such functions. An optimization approach proposes to choose between these functions by comparing them on the basis of a measure of cost. The cost function is a *functional*, a function that maps functions into real numbers. For every movement there is a corresponding number, which provides a basis of com-

parison between movements. The cost function in dynamic optimization generally is taken to be of the following form:

$$J = \int_0^T g(x(t), t) dt, \quad (1)$$

where $g(x(t), t)$ is a function that measures the instantaneous cost of the movement. The instantaneous cost g typically quantifies aspects of the movement that are considered undesirable, such as jerkiness, error, or high-energy expenditure. Integrating the instantaneous cost provides the total measure of cost J .

The mathematical techniques that have been developed for optimizing expressions such as Equation 1 fall into two broad classes: those based on calculus of variations and those based on dynamic programming (Bryson and Ho, 1975). Both classes of techniques provide mathematical conditions that characterize optimal trajectories. For certain classes of problems, these conditions provide equations that can be solved once and for all, yielding closed form expressions for optimal trajectories. For other classes of problems, the equations must be solved numerically.

Note that a description of movement in terms of an optimization principle does not necessarily imply that there is a computational process of optimization underlying the actual control of movement. Optimization theory simply stipulates that the system operates at the minimum of the “cost function” (the measure that is optimized) but does not commit itself to any particular computational process that puts the system at the minimum. Although many possible cost functions have been examined (Nelson, 1983), there are two main classes of models proposed for point-to-point movements—kinematic and dynamic-based models.

KINEMATIC COSTS The cost function in kinematic-based models contain only geometrical and time-based properties of motion, and the variables of interest are the positions (e.g., joint angles or hand Cartesian coordinates) and their corresponding velocities, accelerations, and higher derivatives. Based on the observation that point-to-point movements of the hand are smooth when viewed in a Cartesian framework, it was proposed that the squared first derivative of Cartesian hand acceleration or “jerk” is minimized over the movement (Hogan, 1984; Flash and Hogan, 1985). Letting $x(t)$ denote the position at time t , the minimum jerk model is based on the following cost function:

$$J = \int_0^T \left[\frac{d^3 x}{dt^3} \right]^2 dt, \quad (2)$$

where T is the duration of the movement. Using the calculus of variations, Hogan showed that the trajectory that minimizes this cost function is of the following form:

$$x(t) = x_0 + \frac{1}{6} (x_f - x_0) \left[10(t/T)^3 - 15(t/T)^4 + 6(t/T)^5 \right], \quad (3)$$

where x_0 and x_f are the initial and final positions, respectively.

The minimum jerk model takes the smoothness of motion as the basic primitive and predicts straight-line Cartesian hand paths with bell-shaped velocity profiles that are consistent with empirical data for rapid movements made without accuracy constraints. Flash and Hogan (1985) point out that the natural generalization of Equation 2 to three spatial dimensions involves taking the sum of the squares of the jerk along each dimension, which is equivalent to three independent minimizations. Thus, the resulting trajectories all are of the form of Equation 3, differing only in the values of the initial and final positions. Because these differences simply scale the time-varying part of Equation 3, the result is always a straight-line motion in space. Although penalizing higher derivatives of kinematic variables such as snap, crackle, or pop (the next three derivatives after jerk) produce very similar trajectories, penalizing lower derivatives of kinematic variables, such as acceleration or velocity, lead to nonzero accelerations at the initial time, which is inconsistent with the behavioral data.

One aspect of the minimum jerk model that is unsatisfying is the need to prespecify the duration T . Hoff (1992) has extended the minimum jerk model by allowing the duration to be a free parameter. Because longer movements always can be made smoother than short movements, Hoff created a tradeoff between duration and smoothness by penalizing duration. This is accomplished via the following cost function:

$$J = \int_0^T \left\{ \gamma \left[\frac{d^3 x}{dt^3} \right]^2 + 1 \right\} dt, \quad (4)$$

where T is free. The term of unity in the integrand increases the cost of movements as a function of their duration and trades off against the cost because of smoothness. The parameter γ quantifies the relative magnitudes of these two costs. Hoff has shown that this model can reproduce the results from experiments in which the locations of targets are switched just before the onset of movement (Pelisson et al., 1986; Georgopoulos, Lalaska, and Massey, 1981). The model successfully predicts both movement trajectories and movement duration.

The minimum jerk model recently was used in an attempt to find a unified framework within which to under-

stand two properties of trajectory formation—local isochrony and the two-thirds power law. Whereas “global” isochrony refers to the observation that the average velocity of movements increases with the movement distance, thereby maintaining movement duration nearly constant, “local” isochrony refers to the subunits of movement. For example, if subjects trace out a figure eight in which the two loops are of unequal size, the time to traverse each loop is approximately equal. By approximating the solution of minimum jerk when the path is constrained (only the velocity along the path could be varied), local isochrony becomes an emergent property of the optimization of jerk (Viviani and Flash, 1995). The two-thirds power law, $A \propto C^\beta$ ($\beta \approx \frac{2}{3}$), is based on the observation of the relationship between path curvature (C) and hand angular velocity (A) during drawing or scribbling (Lacquaniti, Terzuolo, and Viviani, 1983) (for a more general formulation of the law, see Viviani and Schneider, 1991). It has been shown that the minimum-jerk solution for movement along a constrained path approximates the solution given by the two-thirds power law (Viviani and Flash, 1995). One area of debate is the extent to which the two-thirds power law is a manifestation of a plan rather than a control constraint. Gribble and Ostry, using a simple dynamic model, have shown that the two-thirds power law could be an emergent property of the viscoelastic properties of the muscles (Gribble and Ostry, 1996). One feature that has not been explained yet by such emergent property models, however, is the fact that the exponent of the power law, β , changes systematically through development, from a value of 0.77 at 6 years of age to an adult value of 0.66 ($\frac{2}{3}$) at approximately 12 years of age (Viviani and Schneider, 1991).

DYNAMIC COSTS The cost function in dynamic-based models depends on the dynamics of the arm, and the variables of interest include joint torques, forces acting on the hand, and muscle commands. Several models have been proposed in which the cost function depends on dynamic variables, such as torque change, muscle tension, or motor command (Kawato, 1992; Uno, Kawato, and Suzuki, 1989). One critical difference between the kinematic and dynamic-based models is the separability of planning and execution. The specification of the movement in kinematic models, such as minimum jerk, involves the positions and velocities of the arm as a function of time. Therefore, a separate process is required to achieve these specifications, and this model is a hierarchical, serial plan-and-execute model. In contrast, the solution to dynamic models, such as minimum torque change, are the motor commands required to achieve the movement, and, therefore, planning and execution are no longer separate processes.

Uno and associates (1989) have presented data that are problematic for the minimum jerk model. First, they studied trajectories when an external force (a spring) acted on the hand. They found that subjects made curvilinear movements in this case, which is not predicted by the minimum jerk model.¹ Second, they studied movements with via points and observed that symmetrically placed via points did not necessarily lead to symmetric paths of the hand in space. Finally, they studied large range movements and observed significant curvilinearity in the paths of motion. These observations led Uno and coworkers to suggest an alternative optimization principle in which forces play a role. They proposed penalizing the rate of change of torque, a quantity that is locally proportional to jerk (under static conditions). This principle is captured by the following cost function:

$$J = \sum_{i=1}^n \left[\frac{d\tau_i}{dt} \right]^2 \quad (5)$$

where $d\tau_i/dt$ is the rate of change of torque at the i th joint. Uno and colleagues showed that this minimum torque-change cost function predicts trajectories that correspond to the trajectories that they observed empirically.

MINIMUM VARIANCE PLANNING Although both minimum jerk and minimum torque-change are able to capture many aspects of observed trajectories, they have several features that make them unsatisfying as models of movement. First, there has been no principled explanation why the CNS should choose to optimize such quantities as jerk or torque-change, other than that these models predict smooth trajectories. These models do not propose any advantage for smoothness of movement but simply assume that smoothness is optimized. Furthermore, it still is unknown whether the CNS could estimate such complex quantities as jerk or torque-change and integrate them over the duration of a trajectory. Lastly, the models provide no principled way of selecting the movement duration, which is a free parameter in both models.

In an attempt to resolve these problems, Harris and Wolpert (1998) recently proposed the minimum-variance theory of motor planning for both eye and arm movements. They suggest that biological noise is the underlying determinant of both eye and arm movement planning. In the model, they assume that the neural control signal is corrupted by noise, thereby causing trajectories to deviate from the desired path. These deviations are accumulated over the duration of a movement, leading to variability in the final position. If the noise were independent of the control signal, then the accumulated error could be minimized by making the movement as

rapidly as possible. However, the key assumption of the hypothesis is that the noise in the neural control signal increases with the mean level of the signal. In the presence of such signal-dependent noise, moving as rapidly as possible actually may increase the variability in the final position. This is because, for low-pass systems such as the eye or arm, moving faster requires larger control signals, which carry more noise. Because the resulting inaccuracy of the movement may require corrective behavior, such as further movements, moving very fast may become counterproductive (Meyer et al., 1988; Harris, 1995). Accuracy could be improved by having small amplitude control signals, but the movement consequently will be slow. Thus, signal-dependent noise inherently imposes a tradeoff between movement duration and terminal accuracy. This is in agreement with the well-known observation that faster arm movements, for a given amplitude, are more inaccurate (Fitts, 1954). The key point is that for given amplitude and duration of movement, the final positional variance depends critically on the actual neural commands and subsequent velocity profile.

Harris and Wolpert (1998) suggest that the feedforward sequence of neural commands are selected to minimize the final positional variance while keeping the duration to the minimum compatible with the accuracy constraints of a particular task. This minimum-variance theory accurately predicts the velocity profiles of both saccades and arm movements (figure 42.4). Moreover, the profiles are relatively insensitive to large changes in the parameters of the arm, so that even when the inertia and viscosity of the arm or the time constants of the muscle are individually halved or doubled, the optimal profile remains essentially unchanged (figure 42.4b). This is consistent with the observation that when the arm is subject to elastic, viscous, or inertial loads, the bell-shaped velocity profile is regained after a period of adaptation (Flash and Gurevich, 1991; Shadmehr and Mussa-Ivaldi, 1994; Lackner and DiZio, 1994; Brashers-Krug, Shadmehr, and Bizzi, 1996; Sainburg and Ghez, 1995; Goodbody and Wolpert, 1998).

The minimum-variance approach has several important ramifications. Primarily, it provides a biologically plausible theoretical underpinning for both eye and arm movements. In contrast, it is difficult to explain the biological relevance of such factors as jerk or torque-change. Moreover, there is no need for the CNS to construct highly derived signals to estimate the cost of the movement, which now is simply variance of the final position or the consequences of this inaccuracy, such as the time spent in making corrective movements (Meyer et al., 1988; Harris, 1995). Such costs are directly available to the nervous system, and the optimal trajectory could

FIGURE 42.4 (a) Theoretical optimal trajectory for minimizing end-point variance with signal-dependent noise for a second-order skeletal model of a one-dimensional arm with inertia 0.25 kg/m^2 and viscosity 0.2 nm/rad driven by a second-order linear muscle with time constants of 30 and 40 ms (parameters taken from van der Helm and Rozendaal, 1998).

(b) Eight velocity profiles for the model in (a) in which the inertia, viscosity, and time constants are individually doubled or halved. The trajectory is essentially invariant to these large changes in the dynamics of the arm. (Reprinted with permission from Harris and Wolpert, 1998.)

be learned from the experience of repeated movements. This model therefore is a combined kinematic and dynamic model. The variance is determined by the dynamics of the system, but the consequences of this variance may be assessed in extrinsic coordinates, such as a visual error. Finally, the model explains why theories based on smoothness have been so successful. To change the velocity of the eye or arm rapidly requires large changes in the driving signal. Because such large signals would generate noise, it pays to avoid abrupt trajectory changes.

Internal models

The basic task of a control system is to manage the relationships between sensory variables and motor variables. There are two basic kinds of transformations that can be considered: sensory-to-motor transformations and motor-to-sensory transformations. The transformation from motor variables to sensory variables is accomplished by the environment and by the musculoskeletal system; these physical systems transform efferent motor actions into reafferent sensory feedback. It is also possible, however, to consider internal transformations, implemented by neural circuitry, that mimic the external motor-to-sensory transformation. Such internal transformations are known as internal forward models. Forward dynamic models predict the next state (e.g., position and velocity), given the current state and the motor command, whereas forward output models predict the sensory feedback. This is in contrast to inverse models, which invert the system by providing the motor command that causes a desired change in state. Because inverse models produce the motor command required to achieve some desired result, they have a natural use as a controller (see the section on Motor Learning).

MOTOR PREDICTION: FORWARD MODELS In this section, we discuss possible roles for forward models in motor control and motor learning (Miall and Wolpert, 1996). One such role is as an ingredient in a system that uses a copy of the motor command—an “efference copy”—to anticipate and cancel the sensory effects of movement—the “reafference.” This role for forward models has been studied extensively in the field of eye movement control (see Jeannerod, 1997, for a review). In the case of limb control, a forward model may subserve the additional function of canceling the effects on sensation induced by self-motion and distinguishing self-produced motion from the sensory feedback caused by contact with objects in the environment.

Another role for forward models is to provide a fast internal loop that helps stabilize feedback control systems. Feedback control in biological systems is subject to potential difficulties with stability because the sensory feedback through the periphery is delayed by a significant amount (Miall et al., 1993). Such delays can result in instability when trying to make rapid movements under feedback control. Two strategies can maintain stability during movement with such delays—intermittence and prediction. Intermittence, in which movement is interspersed with rest, is seen in manual tracking and saccadic eye movement. The intermittence of movement allows time for veridical sensory feedback to be obtained (a strategy often used in adjusting the temperature of a shower, where the time delays are large). Such intermittence can arise either from a psychological refractory period after each movement (Smith, 1967) or from an error deadzone (Wolpert et al., 1992) in which the perceived error must exceed a threshold before a new movement is initiated. Alternatively, in predictive control, a forward model is used to provide internal feedback of the predicted outcome of an action, which can be used before sensory feedback is available, thereby preventing insta-

bility (Miall et al., 1993). In effect, the control system controls the forward model rather than the actual system. Because the loop through the forward model is not subject to peripheral delays, the difficulties with stability are lessened. The control signals obtained within this inner loop are sent to the periphery, and the physical system moves along in tandem. Of course, there are inevitable disturbances acting on the physical system that are not modeled by the internal model; thus, the feedback from the actual system cannot be neglected entirely. However, the predictable feedback can be canceled by delaying the output from the forward model. Only the unpredictable components of the feedback, which are likely to be small, are used in correcting errors within the feedback loop through the periphery. This kind of feedback control system, which uses a forward model both for mimicking the plant and for canceling predictable feedback, is known in the engineering literature as a “Smith predictor.” Miall and associates (1993) have proposed that the cerebellum acts as a Smith predictor.

Another interesting example of a forward model arises in the literature on speech production. Lindblom, Lubker, and Gay (1979) studied an experimental task in which subjects produced vowel sounds while their jaw was held open by a bite block. Lindblom and associates observed that the vowels produced by the subjects had formant frequencies in the normal range, despite the fact that unusual articulatory postures were required to produce these sounds. Moreover, the formant frequencies were in the normal range during the first pitch period, before any possible influence of acoustic feedback. Lindblom and colleagues proposed a model of the control system for speech production that involved placing a forward model of the vocal tract in an internal feedback pathway.

Finally, forward models also can play a role in both state estimation and motor learning, as discussed in the following section.

INVERSE MODELS We also can consider internal models that perform a transformation in the opposite direction, from sensory variables to motor variables. Such transformations are known as *internal inverse models*, and they allow the motor control system to transform desired sensory consequences into the motor actions that yield these consequences. Internal inverse models are the basic modules in open-loop control systems.

Internal inverse models also play an important role in motor control. A particularly clear example of an inverse model arises in the vestibulo-ocular reflex (VOR). The VOR couples the movement of the eyes to the motion of the head, thereby allowing an organism to keep its gaze fixed in space. This is achieved by causing the

motion of the eyes to be equal and opposite to the motion of the head (Robinson, 1981). In effect, the VOR control system must compute the motor command that is predicted to yield a particular eye velocity. This computation is an internal inverse model of the physical relationship between muscle contraction and eye motion.

There are many other such examples of inverse models. Indeed, inverse models are fundamental modules in open-loop control systems: They allow the control system to compute an appropriate control signal without relying on error-correcting feedback.²

An important issue to stress in our discussion of internal models is that internal models are not required to be detailed or accurate models of the external world. Often, an internal model need only provide a rough approximation of some external transformation to play a useful role. For example, an inaccurate inverse model can provide an initial open-loop “push” that is corrected by a feedback controller. Similarly, an inaccurate forward model can be used inside an internal feedback loop because the feedback loop corrects the errors. This issue arises again in the following section, when motor learning is discussed, where we will see that an inaccurate forward model can be used to learn an accurate controller.

State estimation

Although the state of a system is not directly available to the controller, it is possible to estimate the state indirectly. Such a state estimator, known as an “observer” (Goodwin and Sin, 1984), produces its estimate of the current state by monitoring the stream of inputs (motor commands) and outputs (sensory feedback) of the system (figure 42.1). By using both sources of information, the observer can reduce its uncertainty in the state estimate and become robust to sensor failure. In addition, because there are delays in sensory feedback, the observer can use the motor command to produce more timely state estimates than would be possible using sensory feedback alone.

Although many studies have examined integration among purely sensory stimuli (for a psychophysical review, see Welch and Warren, 1986), little is known of how sensory and motor information is integrated during movement. When we move our arm in the absence of visual feedback, there are three basic methods that the CNS can use to obtain an estimate of the current state (e.g., the position and velocity) of the hand. The system can make use of sensory inflow (the information available from proprioception), it can make use of motor outflow (the motor commands sent to the arm), or it can combine these two sources of information. Although sensory signals can directly cue the location of the hand, motor

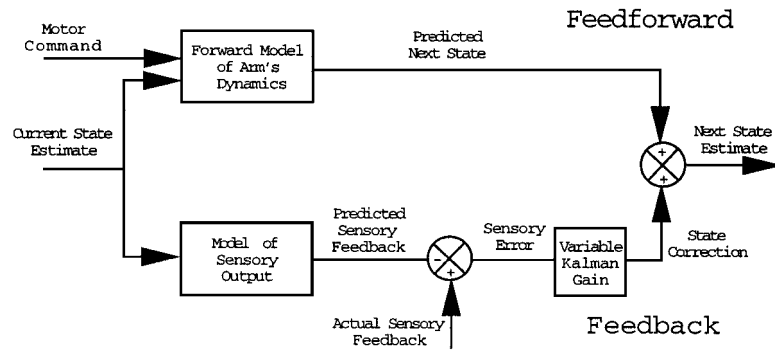

FIGURE 42.5 Sensorimotor integration model. (Reprinted with permission from Wolpert and colleagues, 1995.)

outflow generally does not. For example, given a sequence of torques applied to the arm (the motor outflow), an internal model of the arm's dynamics is needed to estimate the arm's final configuration.

To explore whether an internal model of the arm is used in sensorimotor integration, Wolpert and associates (1995) studied a task in which subjects—after initially viewing their arm in the light—made arm movements in the dark. The subjects' internal estimate of their hand location was assessed by asking them to visually localize the position of their hand (which was hidden from view) at the end of the movement. Wolpert and colleagues developed a model of this sensorimotor integration process (figure 42.5). This Kalman filter model of the sensorimotor integration process is based on a formal engineering model from the optimal state estimation field (Goodwin and Sin, 1984). The Kalman filter is a linear dynamical system that produces an estimate of the location of the hand by using both the motor outflow and sensory feedback in conjunction with a model of the motor system, thereby reducing the overall uncertainty in its estimate (Kalman and Bucy, 1961). This model assumes that the localization errors arise from two sources of uncertainty, the first from the variability in the response of the arm to the motor command and the second in the sensory feedback given the arm's configuration. The Kalman filter model can be considered as the combination of two processes that together contribute to the state estimate. The first, feedforward process (upper part), uses the efferent outflow along with the current state estimate to predict the next state by simulating the movement dynamics with a forward model. The second, feedback process (lower part), compares the sensory inflow with a prediction of the sensory inflow based on the current state. The sensory error, the difference between actual and predicted sensory feedback, is used to correct the state estimate resulting from the forward model. The relative contributions of the internal simulation and sensory correction processes to the final estimate are modulated by the time-varying

Kalman gain to provide optimal state estimates. Unlike simpler models that do not integrate both sensory and motor information, this model could account for the empirical data (Wolpert, Ghahramani, and Jordan, 1995). This suggests that a forward model is used by the CNS to maintain an estimate of the state of the motor system.

Duhamel and colleagues (1992) have presented neurophysiological data that imply a role for an internal forward model in the saccadic system. They have proposed that one of the roles of the lateral intraparietal (LIP) area of the parietal cortex is to maintain a retinal representation of potential saccadic targets. Such a representation simplifies the task of saccade generation because the transformation from a retinal representation to a motor representation is relatively simple. The retinal representation must be updated, however, whenever the eyes move in the head. This updating process requires an internal forward model that embodies knowledge of the retinal effects of eye movements. In particular, for a given eye movement (a motor action), the brain must predict the motion of objects on the retina (the sensory consequences). This predicted motion is added to the current retinal representation to yield an updated retinal representation.

Motor learning

In the previous section, we discussed several ways in which internal models can be used in a control system. Inverse models are the basic building blocks, of open-loop control. Forward models also can be used in open-loop control and have additional roles in state estimation and compensation for delays. An internal model is a form of knowledge about the environment (Ghez et al., 1990; Lacquaniti, Borghese, and Carrozzo, 1992; Shadmehr and Mussa-Ivaldi, 1994). Many motor control problems involve interacting with objects in the external world, and these objects generally have unknown mechanical properties. There also are

changes in the musculoskeletal system due to growth or injury. These considerations suggest an important role for adaptive processes. Through adaptation, the motor control system is able to maintain and update its internal knowledge of external dynamics.

Recent work on motor learning has focused on the representation of the inverse dynamic model. When subjects make point-to-point movements in which the dynamics of their arm is altered, for example, by using a robot to generate a force field acting on the hand, they initially show trajectories that deviate from their normal paths and velocity profiles (Shadmehr and Mussa-Ivaldi, 1994; Lackner and DiZio, 1994). However, over time, subjects adapt and move naturally in the presence of the force field. This can be interpreted as adaptation of the inverse model or the incorporation of an auxiliary control system to counteract the novel forces experienced during movement. Several theoretical questions have been addressed using this learning paradigm. The first explored the representation of the controller and in particular whether it was best represented in joint or Cartesian space (Shadmehr and Mussa-Ivaldi, 1994). This was investigated by examining the generalization of motor learning at locations in the workspace remote from where subjects had adapted to the force field. By assessing in which coordinate system the transfer occurred, evidence was provided for joint-based control. Another important advance was made in a study designed to answer whether the order in which states (position and velocities) were visited was important for learning or whether having learned a force field for a set of states subjects would be able to make natural movements when visiting the states in a novel order (Condit, Gandolfo, and Mussa-Ivaldi, 1997). The findings showed that the order was unimportant and argue strongly against a rote learning of individual trajectories. The learning of novel dynamic has been shown to undergo a period of consolidation after the perturbation has been removed (Brashers-Krug, Shadmehr, and Bizzi, 1996). Subjects' ability to perform in a previously experienced field was disrupted if a different field was presented immediately after this initial experience. Consolidation of this motor learning appears to be a gradual process with a second field after four hours having no effect on subsequent performance in the first field. This suggests that motor learning undergoes a period of consolidation during which time the motor learning or memory is fragile to being disrupted by different motor learning.

In this section, we discuss the computational algorithms by which such motor learning could take place, focusing on five different approaches: direct inverse

FIGURE 42.6 A generic supervised learning system. The vector \mathbf{y} is the actual output, and the vector \mathbf{y}^* is the target output. The error between the target and the actual output is used to adjust the parameters of the learner.

modeling, feedback error learning, distal supervised learning, reinforcement learning, and unsupervised bootstrap learning. All these approaches provide mechanisms for learning general sensorimotor transformations. They differ principally in the kinds of data and the kinds of auxiliary supporting structure that they require.

The first three schemes that we discuss are instances of a general approach to learning known as supervised learning. A generic supervised learning system is shown in figure 42.6. A supervised learner requires a target output corresponding to each input. The error between the target output and the actual output is computed and is used to drive the changes to the parameters inside the learning system. This process generally is formulated as an optimization problem in which the cost function is one-half the squared error:

$$J = \frac{1}{2} \|\mathbf{y}^* - \mathbf{y}\|^2. \quad (6)$$

The learning algorithm adjusts the parameters of the system to minimize this cost function. For details on particular supervised learning algorithms, refer to the study by Hertz and associates (1991).

In the following, we assume that the controlled system or plant (the musculoskeletal system and any relevant external dynamical systems) is described by a set of state variables $\mathbf{x}[n]$, an input $\mathbf{u}[n]$, and an output $\mathbf{y}[n]$. These variables are related by the following dynamic equation:

$$\mathbf{x}[n+1] = f(\mathbf{x}[n], \mathbf{u}[n]). \quad (7)$$

where n is the time step and f is the *next-state equation*. We also require an *output equation* that specifies how the output $\mathbf{y}[n]$ is obtained from the current state:

$$\mathbf{y}[n] = g(\mathbf{x}[n]), \quad (8)$$

We use the notation $\mathbf{y}^*[n]$ to refer to a desired value (a target value) for the output variable and the notation $\hat{\mathbf{x}}[n]$ to refer to an internal estimate of the state of the controlled system.

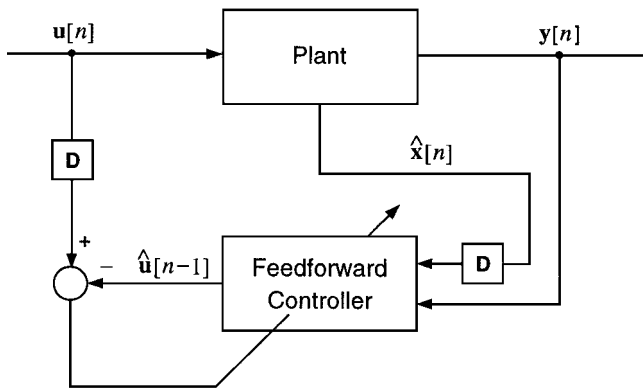

FIGURE 42.7 The direct inverse modeling approach to learning a controller. The state estimate $\hat{\mathbf{x}}[n]$ is assumed to be provided by an observer (not shown).

DIRECT INVERSE MODELING How might a system acquire an inverse model of the plant? One approach is to present various test inputs to the plant, observe the outputs, and provide these input–output pairs as training data to a supervised learning algorithm by reversing the role of the inputs and the outputs. That is, the plant output is provided as an input to the learning controller, and the controller is required to produce as output the corresponding plant input. This approach, shown diagrammatically in figure 42.7, is known as direct inverse modeling (Widrow and Stearns, 1985; Atkeson and Reinkensmeyer, 1988; Kuperstein, 1988; Miller, 1987). Note that we treat the plant output as being observed at time n . The input to the learning controller is the current plant output $\mathbf{y}[n]$ and the delayed state estimate $\hat{\mathbf{x}}[n-1]$. The controller is required to produce the plant input that gave rise to the current output, in the context of the delayed estimated state. This is a supervised learning problem, in which the plant input $\mathbf{u}[n]$ serves as the target in the following cost function:

$$J = \frac{1}{2} \|\mathbf{u}[n] - \hat{\mathbf{u}}[n]\|^2, \quad (9)$$

where $\hat{\mathbf{u}}[n]$ denotes the controller output at time n .

An example of a problem for which the direct inverse modeling approach is applicable is the inverse kinematics problem. The problem is to learn a sensorimotor transformation between the desired position of the hand in spatial coordinates and a corresponding set of joint angles for the arm that achieve that position. To learn such a transformation, the system tries a random joint angle configuration (a vector $\mathbf{u}[n]$) and observes the resulting hand position (the vector $\mathbf{y}[n]$). The system gath-

FIGURE 42.8 (a) An “archery” problem. (b) The parabolic relationship between distance traveled (y) and angle (u) for a projectile. For each value of y , there are two corresponding values of u , symmetrically placed around 45° .

ers a number of such pairs and uses a supervised learning algorithm to learn a mapping from $\mathbf{y}[n]$ to $\mathbf{u}[n]$.

Nonlinear systems and the nonconvexity problem The direct inverse modeling approach is well-behaved for linear systems and indeed can be shown to converge to correct parameter estimates for such systems under certain conditions (Goodwin and Sin, 1984). For nonlinear systems, however, a difficulty arises that is related to the general “degrees-of-freedom problem” in motor control (Bernstein, 1967). The problem is the result of a particular form of redundancy in nonlinear systems (Jordan, 1992). In such systems, the “optimal” parameter estimates (i.e., those that minimize the cost function in Equation 9) in fact may yield an incorrect controller.

Consider the following simple example. Figure 42.8 shows a one degree-of-freedom “archery” problem: A controller chooses an angle u and an arrow is projected at that angle. Figure 42.8b shows the parabolic relationship between distance traveled and angle. Note that for each distance, there are two angles that yield that distance. This implies that a learning system using direct inverse modeling sees two different targets paired with any given input. If a least-squares cost function is used

(see Equation 9), then the system produces an output that is the average of the two targets, which, by the symmetry of the problem, is 45° . Thus, the system converges to an incorrect controller that maps each target distance to the same 45° control signal.

FEEDBACK ERROR LEARNING Kawato and colleagues (1987) have developed a direct approach to motor learning known as *feedback error learning*. Feedback error learning makes use of a feedback controller to guide the learning of the feedforward controller.³ Consider a composite feedback–feedforward control system in which the total control signal is the sum of the feedforward component and the feedback component:

$$\mathbf{u}[n] = \mathbf{u}_{ff}[n] + \mathbf{u}_{fb}[n].$$

In the context of a direct approach to motor learning, the signal $\mathbf{u}[n]$ is the target for learning the feedforward controller (see figure 42.7). The error between the target and the feedforward control signal is $(\mathbf{u}[n] - \mathbf{u}_{ff}[n])$, which in the current case is simply $\mathbf{u}_{fb}[n]$. Thus, an error for learning the feedforward controller can be provided by the feedback control signal (see figure 42.9).

An important difference between feedback error learning and direct inverse modeling regards the signal used as the controller input. In direct inverse modeling, the controller is trained “off-line”; that is, the input to the controller for the purposes of training is the actual plant output, not the desired plant output. For the controller to actually participate in the control process, it must receive the desired plant output as its input. The direct inverse modeling approach therefore requires a switching process—the desired plant output must be switched in for the purposes of control, and the actual plant output must be switched in for the purposes of training. The feedback error learning approach provides a more elegant solution to this problem. In feedback error learning, the desired plant output is used for both control and training. The feedforward controller is trained “on-line”; that is, it is used as a con-

troller while it is being trained. Although the training data that it receives—pairs of actual plant inputs and desired plant outputs—are not samples of the inverse dynamics of the plant, the system nonetheless converges to an inverse model of the plant because of the error-correcting properties of the feedback controller.

By using a feedback controller, the feedback error learning approach also solves another problem associated with direct inverse modeling. Direct inverse modeling is not *goal directed*; that is, it is not sensitive to particular output goals (Jordan and Rosenbaum, 1989). This is seen simply by observing that the goal signal $(\mathbf{y}^*[n])$ does not appear in figure 42.7. The learning process samples randomly in the control space, which may or may not yield a plant output near any particular goal. Even if a particular goal is specified before the learning begins, the direct inverse modeling procedure must search throughout the control space until an acceptable solution is found. In the feedback error learning approach, however, the feedback controller serves to guide the system to the correct region of the control space. By using a feedback controller, the system makes essential use of the error between the desired plant output and the actual plant output to guide the learning. This fact links the feedback error learning approach to the indirect approach to motor learning that we discuss in the following section. In the indirect approach, the learning algorithm is based directly on the output error.

DISTAL SUPERVISED LEARNING In this section, an indirect approach to motor learning known as distal supervised learning is discussed. Distal supervised learning avoids the nonconvexity problem and also avoids certain other problems associated with direct approaches to motor learning (Jordan, 1990; Jordan and Rumelhart, 1992). In distal supervised learning, the controller is learned indirectly, through the intermediary of a forward model of the plant. The forward model must itself be learned from observations of the inputs and outputs of the plant. The distal supervised learning approach

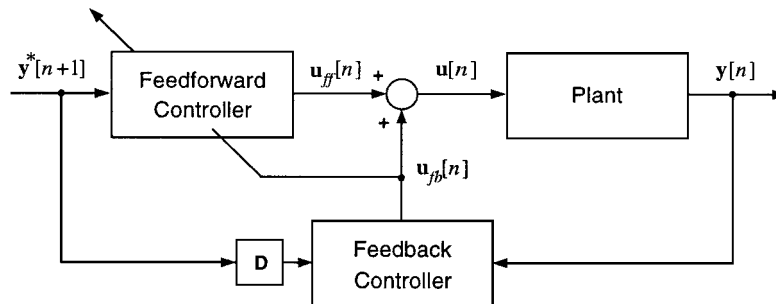

FIGURE 42.9 The feedback error learning approach to learning a feedforward controller. The feedback control signal is the error term for learning the feedforward controller.

therefore is composed of two interacting processes, one process in which the forward model is learned and another process in which the forward model is used in the learning of the controller.

The distal supervised learning approach is illustrated in figure 42.10. There are two interwoven processes depicted in the figure. One process involves the acquisition of an internal forward model of the plant. The forward model is a mapping from states and inputs to predicted plant outputs, and it is trained using the prediction error ($y[n] - \hat{y}[n]$), where $\hat{y}[n]$ is the output of the forward model. The second process involves training the controller. This is accomplished in the following manner. The controller and the forward model are joined together and are treated as a single composite learning system. If the controller is to be an inverse model, then the composite learning system should be an identity transformation (i.e., a transformation whose output is the same as its input). This suggests that the controller can be trained indirectly by training the composite learning system to be an identity transformation. This is a supervised learning problem in which the entire composite learning system (the system inside the dashed box in figure 42.10) corresponds to the box labeled “Learner” in figure 42.6. During this training process, the parameters in the forward model are held fixed. Thus, the composite learning system is trained to be an identity transformation by a constrained learning process in which some of the parameters inside the system are held fixed. By allowing only the controller parameters to be altered, this process trains the controller indirectly.

Training a system to be an identity transformation means that its supervised error signal is the difference

between the input and the output. This error signal is just the *performance error* ($y^*[n] - y[n]$) (see figure 42.10). This is a sensible error term—it is the observed error in motor performance. That is, the learning algorithm trains the controller by correcting the error between the desired plant output and the actual plant output.

Let us return to the “archery” problem. Let us assume that the system already has acquired a perfect forward model of the function relating u to y , as shown in figure 42.11. The system now can use the forward model to recover a solution u for a given target y^* . This can be achieved in different ways, depending on the particular supervised learning technique that is adopted. One approach involves using the local slope of the forward model to provide a correction to the current best guess for the control signal. (This corresponds to using gradient descent as the algorithm for training the composite learning system.) As seen in figure 42.11, the slope provides information about the direction to adjust the control signal to reduce the performance error ($y^* - y$). The adjustments to the control signal are converted into adjustments to the parameters of the controller using the chain rule.

An advantage of working with a forward model is that the nonconvexity of the problem does not prevent the system from converging to a unique solution. The system simply heads downhill toward one solution or the other (see figure 42.11). Moreover, if particular kinds of solutions are preferred (e.g., the left branch vs. the right branch of the parabola), then additional constraints can be added to the cost function to force the system to search in one branch or the other (Jordan, 1990).

FIGURE 42.10 The distal supervised learning approach. The forward model is trained using the prediction error ($y[n] - \hat{y}[n]$). The subsystems in the dashed box constitute the composite learning system. This system is trained by using the performance

error ($y^*[n] - y[n]$) and holding the forward model fixed. The state estimate $\hat{x}[n]$ is assumed to be provided by an observer (not shown).

FIGURE 42.11 A forward model for the archery problem. Given a value of u , the forward model allows the output y to be predicted, the error $y^* - y$ to be estimated, and the slope to be estimated at u . The product of the latter two quantities provides information about how to adjust u to make the error smaller.

Suppose finally that the forward model is imperfect. In this case, the error between the desired output and the predicted output is the quantity $(\mathbf{y}^*[n] - \hat{\mathbf{y}}[n])$, the *predicted performance error*. Using this error, the best the system can do is to acquire a controller that is an inverse of the forward model. Because the forward model is inaccurate, the controller is inaccurate. However, the predicted performance error is not the only error available for training the composite learning system. Because the actual plant output $(\mathbf{y}[n])$ still can be measured after a learning trial, the true performance error $(\mathbf{y}^*[n] - \hat{\mathbf{y}}[n])$ still is available for training the controller. This implies that the output of the forward model can be discarded; the forward model is needed only for the structure that it provides as part of the composite learning system (e.g., the slope that it provides in figure 42.11). Moreover, for this purpose, an exact forward model is not required. Roughly speaking, the forward model need only provide coarse information about how to improve the control signal based on the current performance error, not precise information about how to make the optimal correction. If the performance error is decreased to zero, then an accurate controller has been found, regardless of the path taken to find that controller.

REINFORCEMENT LEARNING Reinforcement learning algorithms differ from supervised learning algorithms by requiring significantly less information be available to the learner. Rather than requiring a vector performance error or a vector target in the control space, reinforcement learning algorithms require only a scalar evaluation of performance. A scalar evaluation signal simply

tells a system whether it is performing well; it does not provide information about how to correct an error. A variety of reinforcement learning algorithms has been developed, and ties have been made to optimal control theory (Sutton and Barto, 1998). A strength of reinforcement learning algorithms is their ability to learn in the face of delayed evaluation.

In the simplest reinforcement learning paradigm, there is a set of possible responses at each point in the state, goal space. Associated with the i th response is a probability of selecting that response as an output on a given trial. Once a response is selected and transmitted to the environment, a scalar evaluation or reinforcement signal is computed as a function of the response and the state of environment. The reinforcement signal then is used in changing the selection probabilities for future trials: If reinforcement is high, the probability of selecting a response is increased; otherwise, the probability is decreased. Typically, the probabilities associated with the remaining (unselected) responses also are adjusted in some manner so that the total probability sums to one.

Reinforcement learning algorithms are able to learn in situations in which very little instructional information is available from the environment. In particular, such algorithms need make no comparison between the input goal (the vector \mathbf{y}^*) and the result obtained (the vector \mathbf{y}) to find a control signal that achieves the goal. When such a comparison can be made, however, reinforcement learning still is applicable but may be slower than other algorithms that make use of such information. Although in many cases in motor control, it appears that a comparison with a goal vector is feasible, the question is empirical and as yet unresolved (Adams, 1984). Does feedback during learning serve to strengthen or weaken the action just emitted or to provide structural information about how to change the action just emitted into a more suitable action?

BOOTSTRAP LEARNING The techniques discussed until this point all require that either an error signal or an evaluation signal is available for adjusting the controller. It also is possible to consider a form of motor learning that needs no such corrective information. This form of learning improves the controller by building on earlier learning. Such an algorithm is referred to in the adaptive signal processing literature as “bootstrap learning” (Widrow and Stearns, 1985).

How might a system learn without being corrected or evaluated? Let us work within the framework discussed previously for reinforcement learning, in which one of a set of responses is chosen with probability p_i . Suppose that because of prior learning, the system performs a task correctly a certain fraction of the time but still

makes errors. The learning algorithm is as follows: The system selects actions according to the probabilities that it already has learned and rewards its actions indiscriminately—that is, it rewards both correct and incorrect actions. We argue that the system still can converge to a control law in which the correct action is chosen with probability one. The reason for this is that the responses of nonselected actions are effectively weakened, because the sum of the p_i must be one. That is, if p_i is strengthened, p_j must be decreased, for all j not equal to i . Because the system starts with the correct action having a larger probability of being selected than the other actions, that action has a larger probability of being strengthened, and thus, an even larger probability of being selected. Thus, if the initial balance in favor of the correct action is strong enough, the system can improve.

We know of no evidence that such a learning process is used by the motor control system, but the possibility appears never to have been investigated directly. The algorithm has intuitive appeal because there are situations in which it seems that mere repetition of a task can lead to improvement. The simplicity of the algorithm certainly is appealing from the point of view of neural implementation.

Modularity

Although the discussion in earlier sections has focused on how a single internal model could be used in motor control, recent models have begun to investigate the computational advantages of using a set of internal models. A general computational strategy for designing modular learning systems is to treat the problem as one of combining multiple models, each of which is defined over a local region of the input space. Such a strategy has been introduced in the “mixture of experts” architecture for supervised learning (Jacobs et al., 1991; Jordan and Jacobs, 1994). The architecture involves a set of function approximators known as “expert networks” (usually neural networks) that are combined by a classifier known as a “gating network” (figure 42.12). These networks are trained simultaneously to split the input space into regions in which particular experts can specialize. The gating network uses a soft split of the input data, thereby allowing data to be processed by multiple experts; the contribution of each is modulated by the gating module’s estimate of the probability that each expert is the appropriate one to use. This model has been proposed both as a model of high-level vision (Jacobs, Jordan, and Barto, 1991) and of the role of the basal ganglia during sensorimotor learning (Graybiel et al., 1994).

Ghahramani and Wolpert (1997) have proposed this model to account for experimental data on visuomotor

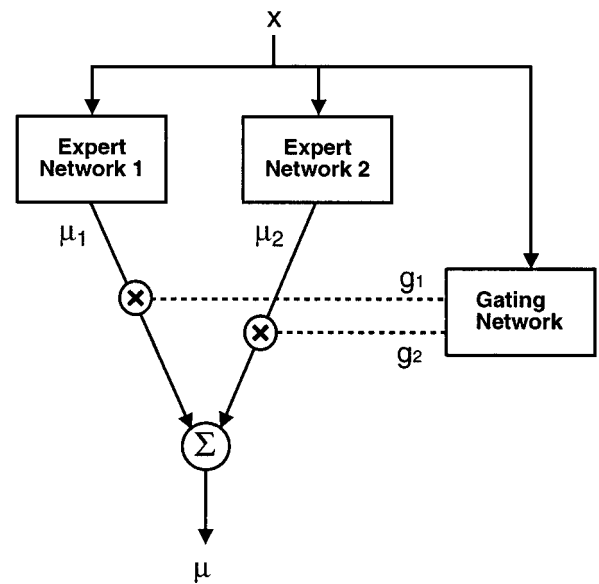

FIGURE 42.12 The mixture of experts architecture. Based on the state vector \mathbf{x} , the gating network assigns credit to the expert networks by calculating normalized mixing coefficients g_i . The expert networks implement a mapping from inputs \mathbf{x} to outputs μ_i for the region of the state space in which they are appropriate.

learning. Using a virtual reality system, a single visual target location was remapped to two different hand positions depending on the starting location of the movement. Such a perturbation creates a conflict in the visuomotor map, which captures the (normally 1-to-1) relation between visually perceived and actual hand locations. One way to resolve this conflict is to develop two separate visuomotor maps (i.e., the expert modules), each appropriate for one of the two starting locations. A separate mechanism (i.e., the gating module) then combines, based on the starting location of the movement, the outputs of the two visuomotor maps. The internal structure of the system was probed by investigating the generalization properties in response to novel inputs, which in this case are the starting locations on which it has not been trained. As predicted by the mixture of experts, model subjects were able to learn both conflicting mappings and to interpolate smoothly from one visuomotor map to the other as the starting location was varied.

MULTIPLE PAIRED FORWARD-INVERSE MODEL There are three potential benefits, with regard to motor control, in employing the modularity inherent in the mixture-of-experts models over a nonmodular system when learning inverse models. First, the world essentially is modular—that is, we interact with multiple qualitatively different objects and environments. By using multiple inverse models, each of which might capture the motor commands necessary when acting with a particular ob-

ject or within a particular environment, we can achieve an efficient coding of the world. In other words, the large set of environmental conditions in which we are required to generate movement requires multiple behaviors or sets of motor commands, each embodied within an inverse model. Second, the use of a modular system allows individual modules to participate in motor learning without affecting the motor behaviors already learned by other modules. Such modularity therefore can reduce interference between what already is learned and what is to be learned, thereby both speeding up motor learning while retaining previously learned behaviors. Third, many situations that we encounter are derived from a combination of previously experienced contexts, such as novel conjoints of manipulated objects and environments. By modulating the contribution to the final motor command of the outputs of the inverse modules, an enormous repertoire of behaviors can be generated. With as few as 32 inverse models, in which the output of each model either contributes or does not contribute to the final motor command, we have 232 or 1010 behaviors—sufficient for a new behavior for every second of one's life. Therefore, multiple internal models can be re-

garded conceptually as motor primitives, which are the building blocks used to construct intricate motor behaviors with an enormous vocabulary.

Given that we wish to use multiple internal models, several questions naturally arise—how are they acquired during motor learning to divide up the repertoire of behaviors for different contexts while preventing new learning from corrupting previously learned behaviors? As at any given time, we usually are faced with a single environment and a single object to be manipulated; the brain must solve the selection problem of issuing a single set of motor commands from its large vocabulary. Thus, how can the outputs of the inverse models be switched on and off appropriately in response to different behavioral contexts to generate a coordinated final motor command?

These issues have been addressed by Wolpert and Kawato (1998) in the multiple paired forward-inverse model. Based on the benefits of a modular approach and the experimental evidence for modularity, Wolpert and Kawato (Wolpert and Kawato, 1998; Kawato and Wolpert, 1998) have proposed that the problem of motor learning and control is best solved using multiple controllers, that is, inverse models. At any given time, one or a subset of these inverse models contributes to the final motor command.

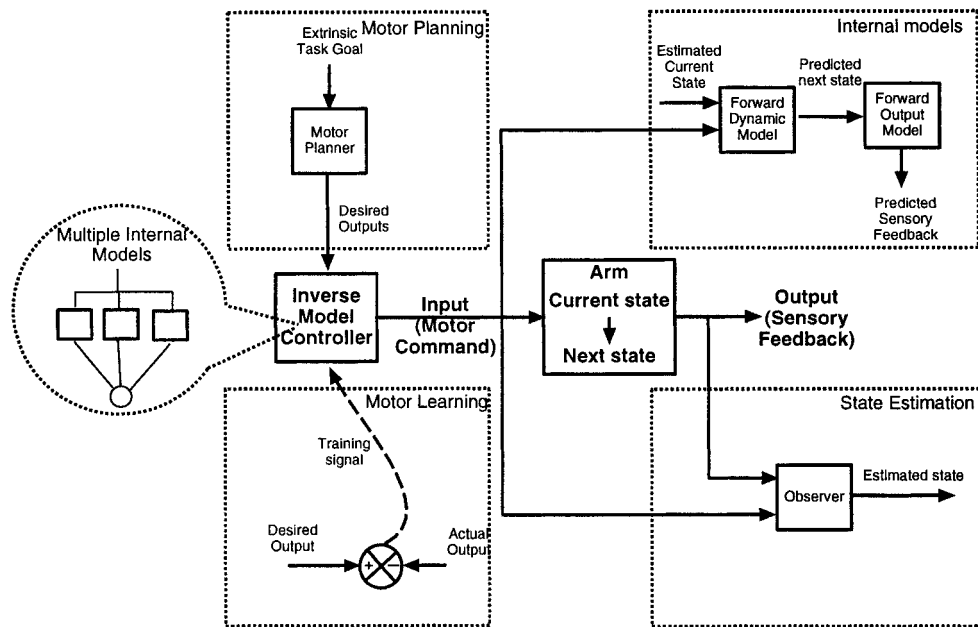

FIGURE 42.13 The multiple paired forward-inverse model. Each inverse model is paired with a corresponding forward model, which is used to convert performance errors into motor errors for training the inverse model. The ensemble of models

is controlled by a “responsibility estimator,” whose job is to partition the state space into regions corresponding to the different local model pairs. Reprinted with permission from Wolpert and Kawato (1998).

The basic idea of the model is that multiple inverse models exist to control the system, and each is augmented with a forward model. The system therefore contains multiple pairs of corresponding forward and inverse models (see figure 42.13). Within each pair, the inverse and forward internal models are coupled tightly during their acquisition, through motor learning and use, through gating of the inverse models' outputs dependent on the behavioral context. Key to this model are the responsibility signals, which reflect, at any given time, the degree to which each pair of forward and inverse models should be responsible for controlling the current behavior. This responsibility signal is derived from the comparison of the errors in prediction of the forward models—the smaller this prediction error, the higher the module's responsibility. The responsibilities then are used to control the learning within the forward models, with those models with high responsibilities receiving proportionally more of their error signals than modules with low responsibility. Over time, the forward models learn to divide up the system dynamics experienced, and the responsibilities reflect the extent to which each forward model captures the current behavior of the system. By using the same responsibility signal to gate the learning of the inverse models, which are updated by a training system such as feedback-error learning, these models learn the appropriate controls for the context captured by their paired forward model. A final component of the model is a responsibility predictor that tries to predict the responsibility of the module from sensory information alone. The responsibility predictor, whose inputs are sensory signals, estimates the responsibility before movement onset, whereas the forward models generate the responsibility after the consequences of movement are known. These two signals are merged to determine the final responsibility estimate, which determines the contribution of each inverse model's output to the final motor command. This combined model is capable of learning to produce appropriate motor commands under a variety of contexts and is able to switch between controllers as the context changes.

NOTES

1. The minimum jerk model is entirely kinematic (forces do not enter into the optimization procedure); thus, it predicts straight-line motion regardless of external forces. This argument assumes that subjects are able in principle to compensate for the external force.

2. Note, however, that inverse models are not the only way to implement open-loop control schemes. As we have seen, an open-loop controller also can be implemented by placing a forward model in an internal feedback loop. See Jordan (1996) for further discussion.
3. A feedforward controller is an internal inverse model of the plant that is used in an open-loop control configuration. See Jordan (1996) for further discussion of feedforward and feedback control.

Introduction

GREGORY J. DIGIROLAMO AND
MICHAEL I. POSNER

Central to human cognition and performance is the ability to selectively enhance the processing of a salient stimulus, relative to less important aspects, in a complex scene. This section addresses the topic of the cognitive and neural mechanisms involved in such attentional selection. The study of the orienting to and selective enhancement of sensory events has been the most explored of all the areas of attention in cognitive neuroscience and this topic dominates our section.

In several chapters (Posner and DiGirolamo; LaBerge; Luck and Hillyard; Robertson and Rafal) a major theme is the processing of a stimulus when multiple stimuli are presented or responses are competing for selection. Investigations into how the brain accomplishes stimulus selection and enhancement have used most of the major methods available to cognitive neuroscience. In the following chapters, you will read about single-cell studies in monkeys demonstrating relative enhancement for stimuli that are attended (Chelazzi and Corbetta), as well as changes in the time course and amplitude of the electrical signal seen on the human scalp for selected stimuli (Luck and Hillyard).

Attention to a stimulus is also accompanied by changes in regional blood flow to the areas of the brain that perform the computations that are being attended (Chelazzi and Corbetta; Mangun, Jha, Hopfinger, and Handy). In addition, the sources of these attentional effects are discussed in several other chapters. LaBerge, in particular, deals with models of how selection might be orchestrated by the interaction of brain regions.

Further chapters concern attentional dysfunction, which impairs the ability to select stimuli due either to brain injury (Behrmann; Robertson and Rafal). The study of patients

with lesions continues to provide an important method for examining the parts of the brain necessary for carrying out attentional functions; it also offers an important basis for applying cognitive neuroscience to the assessment of important human problems and their treatment.

David Marr has pointed out that a complete explanation of any phenomenon must address the mechanisms and the computations involved in carrying out a behavior as well as the behavior itself. Common to all of these chapters, as well as the field of cognitive neuroscience as a whole, is the use of multiple methods of investigation at different levels of analysis to advance our understanding of complex cognitive questions. The problem of integrating data from these multiple levels of analysis remains a frontier for cognitive neuroscience. Mangun and colleagues consider the difficult issue of relating changes in regional cerebral blood flow to the electrical activity recorded from the scalp. These measures also need to be better integrated with the underlying cellular activity and with reaction time studies. Readers need to be careful in following the distinct methods and nomenclatures involved when crossing different levels of analysis. In cognitive psychology, for example, the terms *facilitation* and *inhibition* often refer, respectively, to increases and decreases in reaction time. Improvements in reaction time

may be related either to increases in blood flow due to attention (Chelazzi and Corbetta) or decreases in blood flow due to the tuning of the neural population needed to perform the computation, as in priming or practice. Moreover, increases in blood flow may be caused either by excitatory or inhibitory post-synaptic potentials. Thus the terms at one level may be used quite differently at other levels of analysis. These chapters attempt to explore attentional selection at all levels. A fuller understanding of how terms are employed at each level is important for integration to proceed. New findings are apparent in all of these chapters, but full integration between levels remains extremely difficult.

We have endeavored to gather a range of chapters to demonstrate the progress that has been made in specific areas of attention while giving a broad overview of the field. Some aspects of attention are not addressed in these chapters. For example, our knowledge of the neuroanatomical and neurochemical mechanisms of arousal and sustained attention has progressed considerably. This work was summarized in the last edition of *The Cognitive Neurosciences* by Robbins and Everett and has not been repeated here. Nor have we reexamined the work in development of attention since the summary by Johnson in the last volume.

43 Attention in Cognitive Neuroscience: An Overview

MICHAEL I. POSNER AND GREGORY J. DIGIROLAMO

ABSTRACT The chapters of this section are concerned with the problem of attention. During the past several years, the analysis of attention has progressed substantially in terms of cognitive parameters and brain function. Neuroimaging methods have been applied, singly and in combination, most heavily to the question of orienting to visual targets. The results have yielded a wealth of information showing that attentional modulation occurs rapidly within the visual system, identifying which structures are most heavily involved, and indicating what happens to unattended information. As this effort proceeds, it may be possible to understand more about the anatomy of forms of attention that guide our thoughts, regulate our emotions, and integrate our performance.

Early history

The problem of selective attention is one of the oldest in psychology. William James (1890) wrote, at the turn of the century, "Everyone knows what attention is. It is the taking possession by the mind in clear and vivid form of one out of what seem several simultaneous objects or trains of thought." Even at this very early stage in attentional research, James distinguished between sensory attention driven by external stimuli and voluntary attention to the external environment or internal mental representations.

The dominance of behavioral psychology, however, postponed research into the internal mechanisms of selective attention in the first half of this century. Evidence that the integrity of the reticular formation of the brainstem was important to maintain the alert state provided some anatomical reality to the study of arousal mechanisms underlying one aspect of attention (Moruzzi and Magoun, 1949). This anatomical approach has led to many new findings relating the individual subcortical transmitter systems of arousal (e.g., dopamine, norepinephrine) to the computations underlying the selection of information.

The quest for information-processing mechanisms to support the more selective and voluntary aspects of attention began with studies of dichotic listening following World War II. A filter was proposed that limited the information (in the formal sense of information theory) passed between highly parallel sensory systems and a limited-capacity perceptual system (Broadbent, 1958).

Selective listening experiments supported the view of early selection of a relevant message, with nonselected information being lost to conscious processing. Physiological studies (Skinner and Yingling, 1977) suggested that selection of the relevant channels might involve a thalamic gating mechanism using the reticular nucleus of the thalamus controlled by prefrontal sites. Peripheral gating mechanisms still represent a potential source of selection that might be especially important in lower mammals. In human information-processing studies, however, it was clear that unattended information is often processed to a high level, as evidenced by the fact that an important message on the unattended channel can interfere with the selected channel (Posner, 1978). This result suggested that attentional selection involves higher cortical levels. More recent animal studies suggest that thalamic mechanisms might work in conjunction with sensory processing areas to gate information at cortical levels (LaBerge, this volume; Moran and Desimone, 1985). The ability to select input channels and the levels at which selection occurs has remained an active question of current studies of attention.

In the 1970s, psychologists began to distinguish between automatic and controlled processes (Posner, 1978). Visual words can activate other words similar in meaning (semantic associates), even when the person has no awareness of the word's presence. These studies indicated that the parallel organization found for sensory information extends to semantic processing. However, selecting a word meaning for active attention appeared to suppress the availability of other word meanings. Attention was viewed less as an early sensory bottleneck and more as a system for providing priority for motor acts, consciousness, and memory (Allport, 1980). These higher-level mechanisms of attention

MICHAEL I. POSNER Sackler Institute, Weill Medical College of Cornell University, Ithaca, N.Y.

GREGORY J. DIGIROLAMO Beckman Institute, University of Illinois, Urbana, Ill.

involve frontal areas and provide important means of coordinating cognitive processes (see Chelazzi and Corbetta, chapter 46).

Another approach to selectivity arose in work on the orienting reflex (Kahneman, 1973; Sokolov, 1963). The use of slow autonomic systems (e.g., skin conductance) as a measure of orienting made it difficult to analyze the cognitive components and neural systems underlying orienting. In the mid-1970s, neurobiologists began to study information processing in alert monkeys (Wurtz, Goldberg, and Robinson, 1980). Because the visual system had been relatively well investigated using microelectrodes, much of this work involved the visual system. The last 15 years have seen a steady advance in our understanding of the neural systems related to visual orienting from studies using single-cell recording in alert monkeys (Chelazzi and Corbetta, chapter 46; Motter, 1998). This work demonstrated a relatively restricted number of neural areas in which the firing rates of neurons were enhanced selectively when monkeys were trained to attend to a location or object. At the level of the superior colliculus, selective enhancement could be obtained only when eye movement was involved. In contrast, neurons in the posterior parietal lobe demonstrated selective enhancement even when the animal maintained fixation. An area of the thalamus, the lateral pulvinar, was similar to the parietal lobe in containing cells that demonstrated selective enhancement when monkeys attended (Colby, 1991). Indeed the thalamic areas relate to the earlier rat models (Skinner and Yingling, 1977) but are believed to perform selection at higher levels of analysis. Vision remains the central system for the integration of cognitive and neuroscience approaches to selectivity.

Until recently, the approaches to human information processing differed from neuroscientific approaches to attention using nonhuman animals. The former tended to describe attention either as a bottleneck that protected limited-capacity central systems from overload, or as a resource (analogous to the use of the term in economics) that could be allocated to various processing systems. On the other hand, neuroscientific views emphasized several separate neural mechanisms that might be involved in orienting and maintaining alertness. Currently, there is an attempt to integrate these two viewpoints within the cognitive neuroscience of attention (Näätänen, 1992; Posner and Peterson, 1990). The chapters in this section all take this approach.

Imaging methods

The effort to link attention to specific brain systems depends on the availability of methods to secure links be-

tween cognition and neural processes (Sejnowski and Churchland, 1989). The parameters for classifying methods are based on the spatial resolution and temporal precision of the techniques. Major methods used for spatial resolution include depth electrical recordings, positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). The post-stimulus latency histograms of cells from single- or multi-electrode arrays can provide exquisite temporal and spatial precision, but their invasive nature requires either surgical interventions in humans or the use of animal models. Temporal precision with normal human subjects is a feature of various chronometric methods involving reaction time or speed-accuracy trade-off measures (Bower and Clapper, 1989) and can also be studied by using event-related electrical or magnetic potentials (Näätänen, 1992; Rugg and Coles, 1995).

An important aspect of understanding the current developments in this field is to track converging evidence from multiple methods of study that combine high temporal and spatial resolution (e.g., Heinze et al., 1994). The chapters in this section have been selected to provide a background in various methodologies and perspectives on attention.

Much of the current progress in the cognitive neuroscience of the attention system rests historically on two important methodological developments. First, the use of microelectrodes with alert animals has shown that attention modulates the activity of individual cells (Colby, 1991). Second, anatomical (e.g., computerized tomography or MRI) and physiological (e.g., PET, fMRI) methods of studying parts of the brain have allowed more meaningful investigations of localization of cognitive functions in normal people (Toga and Mazziotta, 1996).

To move beyond the localization of anatomical areas, it is useful to employ methods sensitive to the time dynamics of information processing, and this usually requires analysis in the millisecond range. The temporal precision of various methods is changing rapidly, but the imaging methods based on blood flow or volume require changes in blood vessels, limiting temporal precision to hundreds of milliseconds at best. Currently, combined studies using localization methods (e.g., PET) and time-dynamic methods (e.g., ERPs) provide a convenient way to trace the rapid time-dynamic changes that occur in the course of human information processing (e.g., Heinze et al., 1994).

It would be ideal if imaging methods were developed that provided the desired combination of high temporal and spatial resolution. However, each of the current technologies has its own limitations. Cellular recording is limited to animals and is associated with sampling problems. Magnetoencephalography is expensive and,

unless many channels are used, must be repositioned for examination of each area. Scalp electrical recording suffers from difficulty in localizing the generators directly from scalp distributions, and fMRI and PET are limited by the time required for blood vessels to reflect brain activity (hemodynamic lag). Each of the extant methods will, however, afford modifications that may address some or all of these problems; moreover, new methods, such as event-related fMRI, are becoming available (Josephs, Turner, and Friston, 1997).

Issues

With the exception of advances in methods (e.g., event-related fMRI) and the increased effort to integrate data across methods, much of what was summarized in the previous volume remains up-to-date. The progress in the field, then, relates to the ability to reexamine fundamental issues in light of the new data available from the cognitive neuroscience approach. In that light we address three major issues that arose during the cognitive era—issues that are discussed in more detail in the chapters that follow.

EARLY AND LATE SELECTION One of the oldest issues in the field of attention is how early in processing can attention influence input. Since this issue began during the information-processing period, it often took the following form: Are attentional influences largely changes in criteria (i.e., biases) introduced by the nature of the decisions subjects make based on the sensory evidence, or does attention influence the sensory evidence itself? Many empirical studies were done to determine if attentional changes showed up as alterations in the beta parameter of a signal detection analysis or whether instead they involved changes in the d' parameter (Hawkins et al., 1990). Although many elegant studies were conducted attempting to clarify this issue, no final resolution was reached (although it seems likely that both parameters can be varied by some experimental conditions).

Neuroscience evidence of four types has been brought to bear on these issues: The lesion method (Behrmann, chapter 45; Robertson and Rafal, chapter 44), cellular studies (Chelazzi and Corbetta, chapter 46; Luck and Hillyard, chapter 47), neuroimaging (Chelazzi and Corbetta, chapter 46; Mangun et al., chapter 48) and event-related cortical potentials (Luck and Hillyard, chapter 47; Mangun et al., chapter 48). Lesions of the parietal lobe interfered with the ability to shift attention to the contralesional side and showed a very specific deficit in reaction time experiments (Posner et al., 1987). Stimuli from the affected side appeared to have great difficulty in summoning orienting under conditions when the pa-

tient was already processing something on the ipsilateral side of the lesion (disengage deficit). While normal subjects showed only a small deficit in reaction time when the target appeared in the opposite visual field from the cue (invalid trials), patients were often simply unaware of the target presented in the neglected field. This result seemed decisive evidence of a sensory influence of attention since the subjects with parietal lesions were unable to report the presence of the target.

However, further studies indicated that the neglected stimulus is processed, even if unconsciously, and awareness was still possible. For example, while subjects might miss a contralesional target feature in isolation, they might report the stimulus if integration with material on the ipsilesional side completed an object, even without attention (Driver, Baylis, and Rafal, 1993; Mack and Rock, 1998). Moreover, implicit priming was also reported indicating that many sensory operations were being carried out (McGlinchey-Berroth et al., 1993). In addition to the lesion evidence, both electrical recordings from the scalp and cellular recordings in monkeys in the object recognition pathway indicated that attention could influence portions of the visual systems in V4 and later.

At first, the cellular data were persuasive that V1 could not be influenced by attention. However, attentional modulation in V1 appears to occur when the visual field is cluttered (Posner and Gilbert, 1999). This finding shows how closely the psychological method and the physiological results are integrated. Only in a cluttered field do we usually see extremely strong attentional effects in reaction time experiments in normal subjects. Attentional effects in normals are rarely obtained in an uncluttered field; only neuropsychological patients show a strong effect in an empty field. A cluttered field requires information about the location of the target and also about its surround. This requires selection in a smaller receptive field, and it is then that effects in V1 have been reported (Motter, 1993, 1998).

The early vs. late question can be resolved into three somewhat interdependent issues.

1. How early in the nervous system can attention influence stimulus input? The above results suggest that it can be as early as V1 under some conditions, but it is often later in visual processing (e.g., Moran and Desimone, 1985).

2. How quickly after input can attention influence information processing? Again, the cellular and physiological data indicate that it can be quite early, although in most paradigms the influence is not strong until 80–100 ms after stimulus onset (e.g., Clark and Hillyard, 1996). The timing issue is of particular importance because activation of a particular brain area may be along

the input pathway or could be due to feedback from higher areas.

3. What does early selection mean for the processing of information, both selected and unselected? Here the answer is more complex. It seems to mean that certain aspects of complex scenes may be available for conscious report while other aspects will be available only if they succeed in producing reorienting. Unattended objects, however, may still be processed to fairly high levels, and the processing itself may summon attention. The depth of cognitive processing of unattended objects and the possibility of attentional summoning suggest that early selection does not have the cognitive consequence originally implied. Selecting one stimulus over others does not mean that unselected items will not produce a reorienting of attention (e.g., McCormick, 1997) or still influence behavior (Neill, 1977).

SEPARATE CONTROL SYSTEMS Basic to understanding attention is the issue of whether the mechanisms that comprise the brain's attentional system are separate (James, 1890; Posner and Dehaene, 1994) or not (Neisser, 1976) from sensory and memory systems. Like the issue of early or late selection, this debate stems from cognitive studies of attention. It was apparent that interference would result between tasks requiring common input or output systems (one cannot look forward and backward at the same time, nor flex and extend a muscle simultaneously). However, some evidence suggested that interference occurred in many cognitive studies even when the modality of input and the motor output were quite separate. Many cognitive studies have been related to these issues. But despite evidence on both sides (Bourke, et al., 1996; Duncan, Humphreys, and Ward, 1997), no clear resolution has been possible.

From an anatomical perspective, we can distinguish two types of brain areas related to attention. By the *source* of attention, we mean those anatomical areas that seem to be specific to attention, not primarily involved in other forms of processing. However, when attention operates during task performance, it will operate at the neural areas (*site* of attention) where the computations involved in the task are usually performed. Thus, when subjects attend to the color, form, or motion of a visual object, they amplify blood flow in various extrastriate areas (Corbetta et al., 1991). These areas are known to be involved in the passive registration of the same information. We expect that most brain areas, especially cortical areas, will show attention effects in this sense, although they are not part of the brain's attentional system.

Most discussions of the site vs. source issue have been in the study of orienting (Cohen et al., 1994; Luck and

Ford, 1998; Posner, 1992). Evidence from neglect patients cited in the last section suggested that orienting in the visual system was achieved by orchestrating changes in the orienting network (involving the posterior parietal lobe, pulvinar, and colliculus) to influence input into the ventral object recognition pathway. Thus, visual search would involve changes in the parietal lobe that reflect disengagement, as well as activation in the superior colliculus involved in moving attention; it also provides a signal into V4, via the pulvinar, that enhances information at attended locations (see also LaBerge, chapter 49, for a different but related view). In favor of this view, PET studies show strong activity in parietal, pulvinar, and frontal areas during attention shifts (Corbetta et al., 1995; LaBerge and Buchsbaum, 1990), and ERP data indicate the role of the dorsal pathway during visual search (Luck, 1994).

A different view suggests that attentional effects are primarily due to competition within the object recognition pathway (largely V4) itself (Duncan, Humphreys, and Ward, 1997). This difference may be largely a matter of emphasis, as Desimone and Duncan (1995) allow for top-down influences to be involved in the decision about which part of the scene should be selected. They do not, however, specify what this top-down influence might be (for suggestions on this, see Chelazzi and Corbetta, chapter 46; LaBerge, chapter 49; and Robertson and Rafal, chapter 44).

Even if one acknowledges top-down influences from parietal and frontal areas on the visual system, one may argue that these activations do not constitute a separate attentional system, but rather reflect real or implicit activity of the eyes or some other movement (Rizzolatti, Riggio, and Sheliga, 1994). This view is represented by Chelazzi and Corbetta, chapter 46. There is considerable evidence for anatomical overlap between the frontal and parietal areas used in the control of saccadic eye movements and the areas active during attentional tasks (Corbetta, 1998). Moreover, many important implications about the nature of selective attention have come from the analogy between saccades and attention shifts (for example, the extra time taken to shift across the midline, or the distinction between shifts to the upper and lower visual fields). However, several important pieces of evidence suggest that there are additional properties of attention that do not relate too closely to saccades. First, attention shifts demonstrate costs and benefits even within the fovea (see LaBerge, chapter 49). Second, a shift of attention from the periphery to the fovea has as large a cost as a shift from the fovea to the periphery (Posner and Cohen, 1984). There is also clear evidence for selection among objects in the same visual location (Weber, Kramer, and Miller, 1997). Whether

one thinks of orienting as due to programming of eye movements or as a covert shift within a separate attentional network, the involvement of the parietal area in this process remains to be understood.

The clearest reason for wanting to maintain separation between the brain's attentional system and overt movements, whether of the hands or the eyes, remains situations in which attention is employed to control cognition independent of the effector systems. Searching memory, combining thoughts, selecting information for storage, and monitoring behavior are important attentional operations that require no effector system. These volitional cognitive operations are discussed in the next section.

Executive control

Despite the obvious importance of a means of unifying the processing of anatomically separate cognitive modules, it has been difficult to specify the functions and mechanisms of executive control that lead to coherent behavior. Perhaps for that reason, the cognitive neuroscience literature contains relatively little discussion of these mechanisms. This is also true of this section, although LaBerge (chapter 49 in this volume) discusses some of the frontal input into orienting mechanisms.

Our strongest indication of executive control remains the subjective experience of having control of our thoughts and actions (cf. James, 1890). Lesions of the frontal lobe often produce incoherent behavior and impairment in planning, suggesting an anatomical reality of executive control (Duncan, Burgess, and Emslie, 1995). In this part of our chapter we indicate some effort to extend cognitive models of executive control to neuroimaging studies that explore the anatomy and circuitry of executive control.

It has been hard to define executive control—the term has been used in many ways, and the processes that fall under this umbrella term are not well agreed upon. We try to avoid these difficulties by discussing conflict among stimulus or response elements as one situation in which executive control is needed. Our goal in this section is to review those behavioral and neuroimaging studies of conflict in the Stroop effect, dual task interference, and error detection in the hope of indicating some cognitive and neuroanatomical mechanisms of executive control. At the end, we relate these findings to evidence that the same brain areas may be involved in control of pain, distress, and other emotional responses.

STROOP A classical example of attentional conflict is the well-known Stroop task (Stroop, 1935). In this para-

digm, subjects are asked to name the color of ink in which a word is presented. The word can either indicate a different color name from the ink color (incongruent) or the same color name as the ink color (congruent). The resulting reaction times and error rates are compared against a neutral condition in which a noncolor word or a letter string is presented (see Posner and DiGirolamo, 1998, for a discussion of “neutral”). Highly reliable interference is found when the color and word meaning disagree, and a less reliable but often observed facilitation is found when the color and word agree (MacLeod, 1991).

Neuroimaging studies of the Stroop effect have demonstrated activation of a midline attentional system in resolving the word and color conflict (Bench et al., 1993; Carter, Mintun, and Cohen, 1995; Derbyshire, Vogt, and Jones, 1998; George et al., 1994; Pardo et al., 1990; Taylor et al., 1994). Though the correspondence is not exact, all studies find a midline cingulate activation when the word and color disagree (for a review, see Posner and DiGirolamo, 1998). Surprisingly, the congruent condition (relative to a neutral) also activates the cingulate cortex (Bench et al., 1993; Carter, Mintun, and Cohen, 1995). DiGirolamo (DiGirolamo, Heidrich, and Posner, 1998; Posner and DiGirolamo, 1998) has suggested an analysis of the Stroop effect that postulates comparable selective attentional processes to resolve conflict in both the congruent and incongruent conditions. In support of this hypothesis, event-related potential waveforms for the incongruent and congruent condition diverged from the neutral condition, but did not diverge from each other until response (DiGirolamo, Heidrich, and Posner, 1998). Moreover, dipole modeling of the congruent and incongruent conditions produced matching neural solutions consistent with the cingulate gyrus generator seen in the blood flow studies. These results suggest the activity of an executive attentional system during both congruent and incongruent conditions. Color word trials require a selection between information from the word and information from the color, independent of the congruity of the trial type. These data demonstrate that selection of one dimension of a stimulus that has multiple dimensions presents a situation of conflict that requires executive control mechanisms. In the course of this dimensional conflict, the cingulate cortex is active during times requiring conflict resolution between anatomically separate cognitive processing systems.

DUAL-TASK Neuroimaging studies have suggested that the cingulate cortex is also involved in attentional processing during dual-task situations. When subjects are learning a sequencing task or generating a use for a

word, the cingulate cortex and dorsolateral frontal areas are highly active. In contrast, once performance is automated and attention is no longer required, the cingulate and dorsolateral frontal areas are no longer active (Frith et al., 1991; Raichle et al., 1994). Dual-task interference also decreases when either of the tasks becomes well learned. During dual-task performance of tasks that share neither input nor response, performance deteriorated compared to either task alone, and there was increased activation in the cingulate cortex. Passingham and colleagues (1996) have suggested that interference occurs centrally, not in either perceptual or response systems; they further suggest that one of the neural areas in which the central bottleneck occurs is the cingulate cortex. In support of this notion, when subjects are asked to attend to a well-learned sequence, increased activation is found only in the cingulate and dorsolateral frontal areas and dual-task interference increases. These areas are the same areas active during the original learning of the movement; these areas come back on-line when subjects attend to the movements following practice (Jueptner et al., 1997).

To investigate the central executive of Baddeley's (1993) working memory model, D'Esposito (1995) and colleagues also compared performance in single vs. dual-task conditions. As in the previous study, activation in the cingulate cortex and dorsolateral frontal regions significantly increased (relative to single-task activity) during the concurrent task condition. D'Esposito and colleagues argued that the cingulate cortex and dorsolateral prefrontal cortex comprise part of the neuroanatomical circuit of the central executive.

ERROR DETECTION Immediately following an error, subjects are often conscious of making a mistake. When subjects are aware of making an error in speeded tasks, they showed negativity over midfrontal channels on the scalp following the key press (Dehaene, Posner, and Tucker, 1994; Gehring et al., 1993). Using the Brain Electrical Source Analysis (BESA) algorithm (Scherg and Berg, 1995), localization of this error-related negativity suggested activation from the cingulate (see also Badgaiyan and Posner, 1998). Errors can be either slips (incorrect executions of a motor program) or mistakes (selection of an inappropriate intention). Dehaene, Posner, and Tucker (1994) have shown that the negativity generated by the cingulate only follows a slip when the subjects know they've made an error, but not if they've mistakenly selected an incorrect response. Activation of the cingulate related to conflict and error has now been shown in blood flow studies as well (Carter et al., 1998). Monitoring of the selected response and awareness of the response actually made are crucial for coherent and

successful behavior. Cingulate activation is directly related to awareness of one's own planned behavior.

The presence of frontal activity, particularly in mid-line structures in these conflict tasks, suggests a possible common anatomy, at least to some forms of executive control. In this section we have suggested that these structures are related to subjective feelings of voluntary control of thoughts and feelings. More evidence of this issue arises in studies related to aspects of awareness such as stimuli that involved pain.

PAIN Neuroimaging studies have demonstrated that the processing of pain also activates the anterior cingulate. In a recent study, responses to painful stimuli and to the incongruent trials of the Stroop effect were studied within the same experiment (Derbyshire, Vogt, and Jones, 1998). It was found that areas of the midcingulate were active in both, but that subjects appeared to differ in the specific areas activated to pain and to conflict and the two rarely overlapped in the same subject. Moreover, it appears to be the subjective experience of pain that is encoded in the anterior cingulate. In one study, subjects were hypnotized to experience more or less pain from the same stimulation, dependent on hypnotic suggestion (Rainville et al., 1997). Blood flow changes in the anterior cingulate cortex correlated with subjects' reporting significantly more subjective pain. However, perceived pain did not correlate with activity in primary somatosensory cortex. These findings are intriguing and suggest important interaction between control of cognition and affect (Posner and Rothbart, 1998).

PSYCHIATRIC DISORDERS Another area of investigation to study awareness is the breakdown of volition and perception in psychiatric disorders. One representative case is the positive symptoms of schizophrenia. Symptoms such as alien control and auditory hallucination suggest a dysfunction of the executive control system in patients with schizophrenia (DiGirolamo and Posner, 1996; Early et al., 1989; Frith, 1992). In the positive symptoms of schizophrenia, many of the deficits suggest a dysfunction in subjective perception. Post-mortem histological analysis has revealed abnormalities in cingulate cortex morphology in patients with schizophrenia (Benes, 1993). In Benes' view, the regulatory function of the cingulate is impaired. Neuroimaging studies have suggested that impaired activation in cognitive tasks by patients with schizophrenia are directly related to activation in the cingulate (Dolan et al., 1995). Following neuroleptics, both behavioral performance and blood flow in the cingulate reach the levels seen in subjects with no history of psychiatric disorder. Tracing deficits in the neurocircuitry of psychiatry disorders

might better our understanding of the relation of executive attention functions to normal, as well as pathological, cognition and behavior.

The study of these higher forms of attention from a cognitive neuroscience view is still in an early stage of development. Efforts to better understand the operations involved in executive control as well as to explore their anatomy and circuitry are critical goals for the future of attention research.

44 Disorders of Visual Attention

LYNN C. ROBERTSON AND ROBERT RAFAL

ABSTRACT Advances in cognitive science and neuroscience are leading to a clearer understanding of the psychobiology underlying clinical disorders of visual attention. The study of these disorders has made many contributions to theories of normal attentional functioning, as well. In this chapter we discuss how attentional processes may operate in regulating normal visual attentional operations, explore some of the neural substrates of visual attention, and review the cognitive and biological bases of visual attention disabilities in everyday life. Drawing upon syndrome-based observations, lesion data with neurological patients, and transcortical magnetic stimulation data with normal participants, we examine the contributions of each approach to our understanding of the functions of visual attention and the neural substrates subserving these functions.

Meet the gentleman shown in figure 44.1A (see also color plate 28). He had recently suffered a large stroke affecting the right frontal and parietal lobes. Although his visual sensation was intact, he failed to detect signals in the side of space opposite the lesion and was not consciously aware of contralesional objects or parts of objects. He did not, for example, orient to people who approached him from his left side. And when a \$10 bill was held a few inches from the left side of his face, it went unnoticed. This striking deficiency in lateralized orienting is known as hemispatial neglect. It most commonly results from lesions of the right cerebral hemisphere (although neglect from left hemisphere lesions has been observed), especially those involving the temporoparietal cortex. This chapter covers some of what is known about the psychobiology underlying hemispatial neglect and other clinical disorders of visual attention. The disabilities of these patients pose a vexing puzzle, sometimes challenging existing theories of attention.

Technical advances such as functional magnetic resonance (fMRI), positron emission tomography (PET), and evoked related potentials (ERP) have made it possible to measure regions of activity during visual attention tasks. Findings from these techniques are converging with those from studies of brain-injured subjects, allowing a more complete picture to emerge. In this effort, neuropsychology makes a special contribution: While ac-

tivation studies can determine what brain structures are activated in a given task, only the lesion method can determine what structures are necessary to perform it.

The interpretation of neuropsychological observations as they relate to normal function must consider the dynamic and interactive operations of the brain. While acute lesions eliminate the functions of the destroyed tissue, they also disrupt the functions of neural structures connected to the damaged area. This remote effect is called diaschisis. For example, acute lesions of the frontal cortex may also produce hypometabolism in the superior colliculus (Deuel and Collins, 1984). Thus, the behavioral effects of acute frontal lesions reflect the dysfunction throughout and help to define a frontocollicular circuit, not just the effect of missing frontal tissue. On the other hand, behavior in the chronic phase of illness, after acute diaschisis effects have abated, may reflect the operations of a reorganized brain. These changes in behavior during the transition from acute to chronic phases of disability can provide precious insights into dynamic brain organization.

The recent application of the technique of transcranial magnetic stimulation (TMS) in cognitive neuroscience provides converging lesion data that can help in interpreting the effects of natural lesions. TMS is used to induce an electric current through the skull on subjacent cortex, and can thus be used with normal subjects. After briefly activating the cortex, there is a silent period, lasting less than a few hundred milliseconds, in which the cortex is transiently inactivated. TMS essentially induces an ultra-acute lesion—one that is very brief and is not susceptible to plastic brain reorganization, so diaschisis of remote structures is not likely.

In this chapter we examine some of the effects of both acute and chronic lesions, and of TMS on selected aspects of visual attention. We first review the role of specific brain structures in orienting attention to locations in the visual field with some potential links to eye movement systems. Then we consider the role objects may play in guiding attention.

The visual grasp reflex

All vertebrates have primitive midbrain circuits for reflexively orienting toward salient events in the visual

FIGURE 44.1 (A) A patient with left hemispatial neglect from a recent frontoparietal stroke. He is not aware of the examiner approaching from the left side. Note the orienting bias toward his right ipsilesional side. (B) A patient with progressive supra-

nuclear palsy (PSP). He is aware of the examiner but has lost the spontaneous visual grasp reflex, even when the examiner looms toward him.

periphery. As mammals, humans have a phylogenetically new visual cortex that receives its dominant input through the thalamus (the lateral geniculate nucleus). The phylogenetically older midbrain pathway in humans is most associated with eye movements that normally accompany visual orienting. Figure 44.1B shows a patient with a neurodegenerative disorder of the brain stem and basal ganglia—a disorder known as progressive supranuclear palsy (PSP). Because the basal ganglia and the substantia nigra are involved, the clinical picture shares many features with Parkinson's disease. In addition, there is degeneration unique to this disease involving the superior colliculus and adjacent peritectal region. This pathology results in the distinctive paralysis of voluntary eye movements. Although there is a loss of the spontaneous visual grasp reflex, the patient is not blind and, unlike the patient with hemispatial neglect in figure 44.1A, he does report seeing the examiner.

In a study of attentional orienting, PSP patients were asked to respond with a key press when they detected a target appearing to the left, right, above, or below fixation (Posner et al., 1985; Rafal et al., 1988). Before each target, a peripheral cue appeared at one of these locations, and the influence of the cue on subsequent detection speed was measured. In normal individuals, the cue produces a biphasic effect on target detection; early facilitation followed by later inhibition, known as inhibition of return or IOR. The PSP patients exhibited a loss of both the initial facilitatory effect and the IOR along the vertical axis where their voluntary eye movement deficits were most severe. Thus both components of reflexive orienting seem to be mediated, at least in part, by midbrain visuomotor pathways.

Another way to investigate midbrain visuomotor reflexes in humans is to determine what visuomotor functions are preserved when damage to primary visual (striate) cortex leaves midbrain pathways intact. Figure 44.2A shows the MRI of an individual whose small stroke in the pericalcarine cortex was largely restricted to this area. Unlike the patients in figure 44.1, this patient is blind in the entire hemifield contralateral to the lesion. The capacity of patients with such visual loss to compensate is striking—a capacity that may be mediated in part by preserved retinotectal pathways. These pathways process information that, while not accessible to awareness, can nevertheless trigger orienting responses toward the hemianopic field. This “blindsight” has been demonstrated by requiring hemianopic subjects to move their eyes or reach toward signals they cannot “see,” and by employing forced-choice response methods to show that visual information is processed without awareness (Weiskrantz, 1986).

The physiologic mechanisms responsible for blindsight remain controversial. In some patients there is “residual vision,” which could be mediated by spared geniculostriate fibers (Fendrich, Wessinger, and Gazzaniga, 1992). Recently, however, Danziger, Fendrich, and Rafal (1997) showed that IOR was activated in the blind field of a hemianopic patient, even in regions that did not show conventional blindsight on a forced-choice localization task. This finding offers converging evidence that visual orienting is generated through midbrain visuomotor pathways.

CORTICOCOLLICULAR INTERACTIONS There are extensive direct and indirect projections from the cortex to the superior colliculus. This is especially prominent for areas of the dorsolateral prefrontal cortex, most notably the frontal eye field (FEF), but is also true for parietal-occipital areas.

Parietocollicular interactions Parietal influence on collicular activity was demonstrated some time ago in cats (Sprague, 1966). Behavior akin to hemispatial neglect of the contralesional side was induced by removing occipital and parietal cortex on one side. However, subsequent removal of the opposite superior colliculus improved vision in the contralesional field. This phenomenon, known as the Sprague effect, suggests that the parieto-occipital projections into the ipsilateral superior colliculus normally exert tonic facilitation. After parietal lesions, the ipsilesional colliculus loses this tonic activation (Hovda and Villablanca, 1990). At the same time, the opposite (contralesional) colliculus becomes hyperactive due to increased activation from its parietal lobe—the consequence of decreased inhibition through callosal projections from the opposite hemisphere (Seyal, Ro, and Rafal, 1995). The two colliculi are mutually inhibitory under normal conditions; i.e., the more active the colliculus is on one side, the more inhibition it exerts on the other. In this way, the colliculus that is normally activated by ipsilateral parieto-occipital projections receives a double hit with unilateral parietal lesions. Not only does the activation of the ipsilesional colliculus decrease due to the cortical damage, but it also decreases due to increased inhibition from the opposite superior colliculus.

Frontocollicular interactions Hemispatial neglect also occurs with acute frontal lobe damage and is often accompanied by eye deviation toward the ipsilesional side. An acute lesion to the FEF causes a kind of shock to connected regions (i.e., diaschisis), which can be measured experimentally as hypometabolism in remote structures including the superior colliculus (Deuel and Collins,

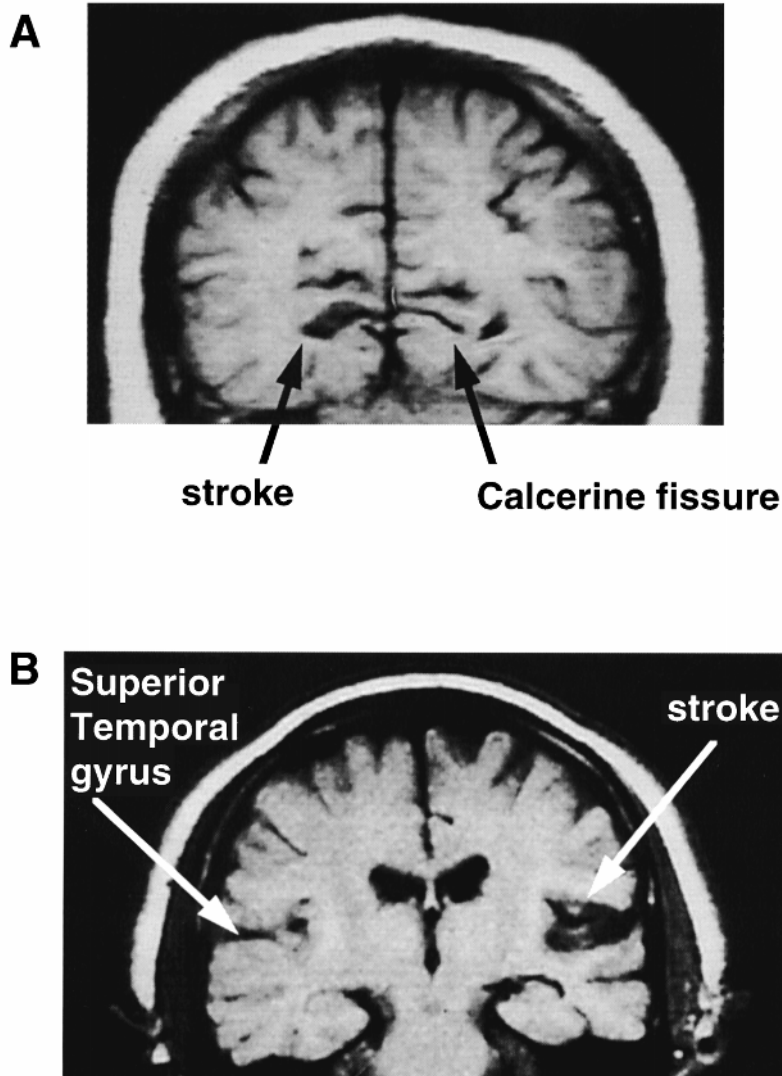

FIGURE 44.2 MRI scans of patients with (A) a small striate cortex lesion causing hemianopia and (B) a small temporal-parietal lesion.

1984). Neglect seen after small acute lesions of the FEF is generally short-term, and may be due in part to transient ipsilesional colliculus dysfunction. In the chronic, compensated state, lesions restricted to the FEF result neither in persistent neglect nor any other evident impairments in daily life. The reorganized state of frontocollicular circuitry after FEF lesions is a complex one. One of the net effects of chronic FEF lesions may be a disinhibited visual grasp reflex toward contralesional signals (i.e., the opposite of what is seen in neglect). This can be seen in the eye movements of recovered patients with frontal lesions in anti-saccade tasks. That is, chronic lesions in the FEF produce a deficit in inhibiting reflexive glances, especially into the contralesional field (Guitton, Buchtel, and Douglas, 1985; Rafal et al., in press).

Henik, Rafal, and Rhodes, 1994 compared the effects of chronic unilateral lesions of the human frontal eye fields on the latencies of reflexive visually guided saccades and of voluntary saccades. The patients in this study were part of a pool of individuals who had suffered brain injuries some time earlier, mostly from strokes, and who have been gracious in helping us investigate the consequences of these injuries. Each was selected for having a single, unilateral lesion restricted to the dorsolateral prefrontal cortex. Nine patients in whom the lesion included the FEF were compared with seven neurological control patients who had frontal lesions that spared what is believed, on the basis of PET studies, to be the human analog to the FEF (Paus, 1996).

The patients were tested in two saccade tasks: visually guided saccades to targets that appeared 10 degrees to the left or right, and voluntary saccades from a symbolic arrow cue at the center of the display that pointed to a marker target 10 degrees to the left or right. For the neurological patients whose frontal lesions spared the FEF, the latencies for voluntary saccades were normal, i.e., longer than for visually guided saccades, and the frontal lesion did not produce an asymmetry in eye movements for one direction over another. In patients with FEF lesions, voluntary saccades were slower to the contralesional field. In contrast, reflexive, visually guided saccades were slower to the ipsilesional field. In addition, in the ipsilesional field the patients' visually guided saccade latencies were no faster than their latencies for voluntary saccades.

These results indicate that FEF lesions have two separate effects on eye movements: (1) They increase the latency of endogenous saccades, and are thus involved in their generation; (2) they reduce the visual grasp reflex in the ipsilesional field relative to the contralesional field after recovery. Thus unilateral lesions of the FEF, in the chronic state, can produce a kind of reverse Sprague effect. One explanation is that FEF lesions disinhibit the ipsilesional substantia nigra pars reticulata, resulting in inhibition of the superior colliculus opposite to the FEF lesion.

A study using transcranial magnetic stimulation (TMS) in normal subjects investigated whether this reverse Sprague effect reflects a reorganization following recovery from brain injury or the immediate effect of FEF inactivation. The effects of TMS are very transient. They presumably do not cause much in the way of remote diaschisis effects and certainly do not allow time for reorganization. When TMS was applied over the FEF, there was an increase in latency for voluntary saccades to the contralateral field—the same pattern that was seen in patients with chronic focal lesions (Ro et al., 1997). However, TMS of the FEF did not have the effect on ipsilesional visually guided saccades that occurs with chronic lesions, suggesting that the reverse Sprague effect after chronic FEF lesions is the result of reorganization or compensation from brain injury.

These findings emphasize the importance of converging approaches to studies in cognitive neuroscience; the study of both acute and chronic lesions can be revealing when the findings of both kinds of investigations are integrated with one another and with other methods for studying brain function in humans. A recent study (Ro et al., 1999) combined TMS and MRI imaging to map the human frontal eye field. The hand area of motor cortex was identified physiologically as the focal region where TMS elicited finger movements. A marker was

placed over this scalp site and an MRI scan was taken to co-localize the hand with morphological markers on MRI (see figure 44.3). The region just anterior to the hand area was mapped to identify sites where TMS increased the latency for voluntary saccades. The results confirmed the region as centered about 2 cm anterior to the hand at the junction of the middle frontal gyrus and the precentral gyrus. The excellent spatial resolution of TMS and its ultra-brief effects—which obviate the problems of diaschisis and plastic brain reorganization that can complicate the interpretation of the effects of natural lesions in the acute and chronic stages, respectively—make it a promising technique for providing converging information about brain-behavior relationships.

Disengaging attention and the mechanism of extinction

Extinction is associated with hemispatial neglect. Patients with extinction report no information on the contralesional side but only when there is simultaneous stimulation on the ipsilesional side. One initial explanation of this phenomenon focused on attention and a “disengage deficit”; that is, patients have difficulty disengaging attention from an ipsilesional stimulus to move in the direction of a contralesional stimulus (Posner et al., 1984). Thus, when a cue was presented on the ipsilesional or contralesional side, response time to detect a target at the cued location (valid) was rapid, but response time to detect a target at the uncued location (invalid) was much greater when first cued to the ipsilesional side.

Posner and colleagues (1984) suggested that the deficit was more pronounced in patients with superior parietal lesions. However, a more recent study with patients with chronic focal lesions (Friedrich et al., 1998) has implicated the temporal-parietal junction (TPJ) (figure 44.2B) as the critical region in producing a pattern consistent with a disengage deficit.

Space and objects

What is it that is neglected in patients like the gentleman in figure 44.1A? Marlene Behrmann provides an excellent review in her chapter (chapter 45 in this volume) showing that perceptual processing can proceed in object-centered reference frames (i.e., spatial representations defined by objects, scenes, or groups of items). Here we discuss selected findings that may help determine how reference frames are established and how attention is distributed within these frames.

Object-centered neglect can be observed at bedside when the examiner rotates 90 degrees right or left in

FIGURE 44.3 Structural MRI of normal subject showing the hand area of the motor cortex (white crosshairs), where transcortical magnetic stimulation (TMS) produced finger movements, and oculomotor cortex (outlined crosshairs), where TMS resulted in increased latency for voluntary sac-

ades to the contralateral visual field. The white crosshairs are represented in the upper figure as a white dot surrounded by a black square, and the outlined crosshairs are represented by the black form outlined in white to its right. (Adapted from Ro et al., 1999.)

front of a patient, as shown in figure 44.4. In this case, evidence for neglect in nonviewer spatial frames is observed relative to right and left defined by the examiner's orientation. For lack of a better word, such effects are commonly described as "object-based," since neglect for one side of space follows a stimulus—a face, a screen, or even a higher-order collection of parts that form a more

global perceptual unit. Object-based neglect highlights a paradox. Neglect is defined as the lack of awareness for space in objects or parts of objects, yet objects are the very things that define the space for object-based neglect. How this occurs is not yet known, but there are several lines of evidence that give some hints about what information may be critical.

FIGURE 44.4 A patient with unilateral visual neglect who neglects the right hand of the examiner (the hand on the patient's left side when both patient and examiner are upright) in coordinates defined by the orientation of the examiner's body. The

Grabowecky, Robertson, and Treisman (1993) demonstrated that the represented center of a display can be manipulated by varying the center of mass. Seven patients with neglect were asked to visually search a diamond-shaped area for a target in the center of a display. The central display was either presented alone or with nontarget flankers on the right or left side or both (figure 44.5). Relative to the no-flanker condition, neglect was magnified when flankers were placed on the ipsilesional side, thereby moving the central diamond display further to the contralesional side in object-centered coordinates. But when flankers were added to both the contralesional and ipsilesional sides, the magnitude of neglect reverted to that observed when no flankers were present. This occurred whether or not the flankers contained features of the target (Grabowecky, 1992). In other words, it was not the absolute amount of information in the ipsilesional or contralesional visual field that was most important in establishing the center of the reference frame—it was the center of mass of the display in object-based coordinates.

Pavlovskaya and colleagues (1997) have shown that one critical determinant of the center of mass is the display's luminance centroid (LC), which they calculate on the basis of the low spatial frequency information in the display. They found that normal participants detected targets located at the LC more readily than they detected targets at the center defined by spatial geometry (when the two defined different locations, and hence were pitted against each other) or at other locations within the display. Targets slightly to the left or right of the LC were detected relatively poorly. And, in two patients with neglect, the patients' attention was shifted to

examiner's right hand is neglected even when his body is rotated 90 degrees to the right or the left. This is an example of neglect in object-centered coordinates. (Reprinted from Rafal, 1994.)

FIGURE 44.5 Example of stimuli used with a group of neglect patients in a conjunction search task where the target was always in a diamond-like 4×4 matrix presented in the center of the screen. Flankers where targets never appeared were either not present (A), present on the right or left side only (B, C), or present on both sides (D). The center of mass varies with these different displays and neglect varied with the center of mass.

the right of the LC. These findings suggest there may be a critical role of lower spatial frequencies in determining the center of a reference frame or its origin. Moreover, these effects have implications for the role of the right hemisphere in global processing.

These results are consistent with those of Driver and co-workers (1993), who showed that symmetry of a display influences performance in patients with neglect, even when they cannot report whether or not a stimulus

FIGURE 44.6 Example of a figure–ground pattern where the normal propensity is to perceive the symmetric design as figure. A patient with neglect reported by Driver, Baylis, and Ra-

fal (1993) also experienced figure–ground segmentation based on symmetry in this figure, even though he was at chance in explicitly reporting whether or not the shapes were symmetric.

is symmetric. (In a symmetric figure, the center of mass and LC are always in the middle.) They exploited the well known phenomenon in normals that symmetric figures are more likely than asymmetric ones to be seen as figure in a figure–ground display (figure 44.6). A patient with neglect was instructed to report which of two colors appeared in front of the other in a figure–ground pattern. The patient chose the color of the symmetric figure

more often than that of the asymmetric figure, even though he could not correctly report whether the color he chose was that of a symmetric or asymmetric figure.

The foregoing observations add to the evidence that, in the neglected field, preattentive vision can parse a scene to extract figure from ground, group objects, and define their primary axis. The center of mass is then shifted to produce an attentional shift to the right in

FIGURE 44.7 Early visual processing in neglect. (A) Figures used by Mattingley, Davis, and Driver (1997) to show that amodal completion behind an occluder reduced visual extinction. (B) Figures used by Ro and Rafal (1996) to demonstrate that geometric illusions are generated preattentively. The two figures on the bottom demonstrate the Muller-Lyer illusion, and show that the patient's bisection error (the bisection mark is shown in gray and the true midpoint in black) was proportional to perceived line length as determined by the illusion. The top and bottom figures in each pair differ only on the left (contralesional) side and were reported as looking the "same" by the patient. Nevertheless, her bisection errors differed in top and bottom pairs, demonstrating that the illusions were generated by features on the left for which the patient had no explicit awareness. Bisection errors are indicated in millimeters (standard deviations in parentheses).

object-centered reference frames. As observed in unilateral visual neglect, this shift can cause information on the contralesional edge of a stimulus to drop from conscious awareness. Other observations in patients with hemispatial neglect demonstrate that early or preattentive vision generates amodal completion (Mattingley, Davis, and Driver, 1997; figure 44.7A) as well as geometric illusions (Ro and Rafal, 1996; figure 44.7B). What is neglected by some patients appears to be the contralesional side of reference frames within candidate objects.

Finally, other effects have shown hemispheric differences in attentional orienting within rather than between objects of a display. Egly, Driver, and Rafal (1994) used a modification of the covert orienting paradigm to mea-

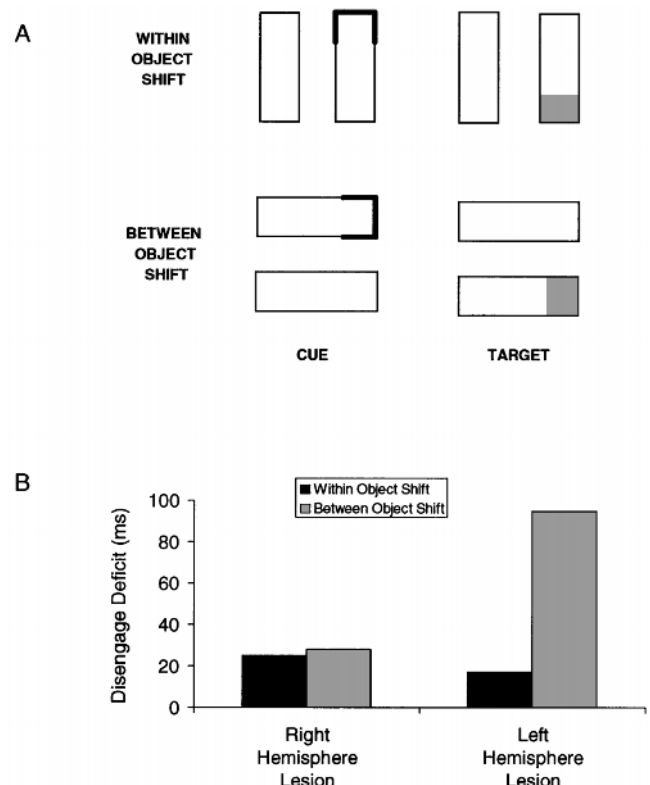

FIGURE 44.8 (A) Example of stimuli adapted from Egly, Driver, and Rafal (1994). A location at one end of a rectangle is cued (dark black lines) and a target (gray filled square) appears 300 ms later. The target is more likely to be at the cued location (valid) than uncued location (invalid), which occurs either within the same object or between objects as shown. (B) Data for groups of patients with left parietal lesions ($N=5$) or right parietal lesions ($N=8$). The disengage deficit refers to the mean RT costs (invalid minus valid) for ipsilesional minus contralesional shifts of attention. (Adapted from Rafal and Robertson, 1995.)

sure what has come to be called space- and object-based attentional shifts. They tested normal subjects and patients with chronic lesions of the posterior parietal association cortex. The stimuli and procedure are outlined in figure 44.8. In normal subjects, cueing effects (or costs) were greater for shifting attention between than within objects. Several findings in the patient groups are noteworthy. First, both patient groups (those with left- or right-hemisphere lesions) produced larger costs to respond to targets in their contralesional than their ipsilesional fields. This is consistent with the LC and center of mass results just discussed. The important new finding was a difference between the two patient groups in shifting attention between objects. Both patient groups showed problems in disengaging attention from the intact field; however, for between-object shifts of attention from the ipsilesional to the contralesional field, the

disengage deficit in patients with left-hemisphere damage was more pronounced than in patients with right-hemisphere damage.

Another study using a similar paradigm confirmed the hemispheric differences in a split-brain patient. When the stimuli were presented in his left visual field, between- and within-object shifts were equivalent (attention was guided by the overall or global stimulus array). But when the stimuli were presented in his right visual field, the normal within- versus between-object differences were observed (Egley, Driver, and Rafal, 1994).

Taken together, these findings suggest that the left parietal lobe is critical for shifting attention between objects (perhaps from one center of mass to another), while the right parietal lobe is more involved in shifting attention within global aspects of a stimulus display. Indeed, shifting attention between global and local objects is also affected by left but not by right parietal lesions (see Robertson, 1996; Rafal and Robertson, 1995), consistent with a problem in shifting attention between LCs defined by global properties of a stimulus and those defined by more local properties.

Objects and parts of objects

In the natural environment, spatial relationships are often complex. Objects are not merely next to each other, with spatial gaps between them; some objects contain other objects or form parts of one another. The focus of attention in any given display may vary. In natural scenes attention can be directed to a house, to its windows and doors, to a wall to the material from which the wall is made, and so on. Neuropsychological evidence has shown that global and local object structure is processed differently by the two hemispheres.

Right-hemisphere damage disrupts (eliminates or slows) the perception of global objects, while left-hemisphere damage disrupts the perception of local objects (or what is typically called parts). Figure 44.9 shows an example of the drawings from patients with unilateral left- or right-hemisphere damage (Delis, Robertson, and Efron, 1986; Robertson and Lamb, 1991). These dramatic differences were observed in patients in acute stages. When groups of well-screened and stable neurological patients were tested well after stroke (from 6 months to 13 years), the hemispheric differences were revealed only in response time measures. In these studies the stimuli were large global letters constructed from smaller local letters shown briefly on a computer screen. The task was to determine, as rapidly as possible, which of two target letters occurred on each trial. The target appeared as either the global or local form and response

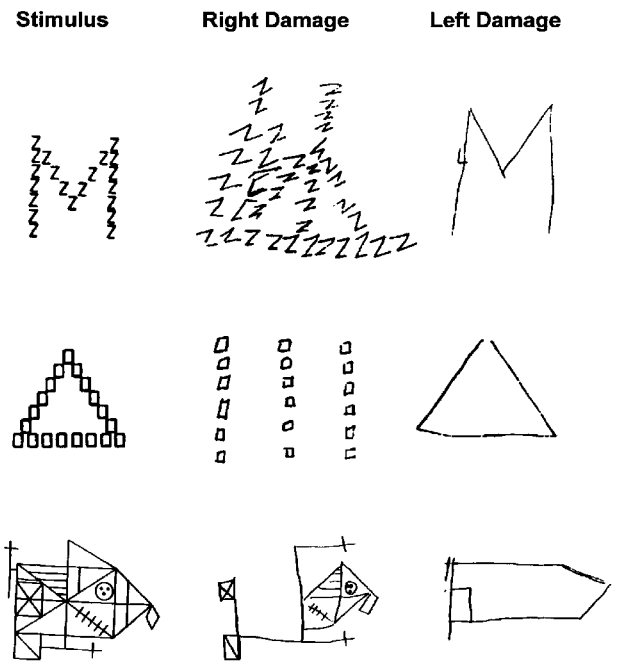

FIGURE 44.9 Examples of drawings of a stimulus by patients with left or right hemisphere damage. (Adapted from Robertson and Lamb, 1991.)

time was measured via computer. Six groups of patients ($N = 5-7$) and normal matched controls were tested (Robertson, Lamb, and Knight, 1988, 1991). The hemispheric differences were found only for patients with lesions that were centered in the temporal-parietal junction (TPJ).

The hemispheric differences cannot be attributed to the sensory acuity of the global and local objects. The global/local asymmetry has been observed in TPJ groups whether the stimuli are shown in central vision, where acuity is high, or in peripheral vision, where it is low. Visual resolution falls off rapidly in sensory and primary vision as one moves out from the fovea, and local discrimination suffers more than global discrimination as resolution decreases. Nevertheless, the hemispheric effects remain relatively unaffected. The hemispheric effects also occur in patients whether the stimuli are presented in central vision or in the contralateral or ipsilateral visual field to the lesion (see Ivry and Robertson, 1998, for a complete discussion). Although the baseline speed of response may change (local discrimination is faster in central than peripheral vision), the asymmetry continues to be observed relative to a baseline established by control subjects.

Another study showed that the differences remained strong for centrally presented stimuli even when the stimulus changed in overall size (Lamb, Robertson, and Knight, 1990). Again, the hemispheric

asymmetry was relative to the baseline response of normal age-matched controls and was found only for TPJ groups. Together, these results demonstrate that the asymmetry is superimposed on primary visual processes that may favor one stimulus size or spatial scale over another.

Initial studies with normal healthy subjects suggested that the differences were due to the different spatial frequency spectra that define global and local objects. This difference is roughly equivalent to spatial resolution (blurry vs. fine) or spatial scale (large vs. small). The spatial frequency hypothesis was originally proposed by Sergent (1982), who used hierarchical letter patterns presented briefly in either the right or left visual field in normal, college-aged students. Left visual field presentation (projecting stimuli directly to the right hemisphere) produced faster responses for global letters, while right visual field presentation (projecting stimuli directly to the left hemisphere) produced faster responses for local letters.

Kitterle, Christman, and Hellige (1990) tested this hypothesis in healthy normal subjects by presenting sinusoidal gratings with a single spatial frequency per trial in either the right or left visual field. They first used a simple detection task, and found no evidence of visual field differences. However, when subjects had to determine which grating was presented (i.e., attend to the spatial frequencies in the stimulus in order to determine which one it was), response times differed. Response times for lower frequencies were better when presented in the left visual field (LVF) than the right visual field (RVF), while response times for higher frequencies were better when presented in the RVF than the LVF. As global objects include lower frequencies than local objects, these data are consistent with the global/local differences found by Sergent but occur only when the object level is important in performing the task (i.e., attention to particular frequencies is useful).

But if this hypothesis is correct, how do we account for the invariance of the asymmetry in TPJ patients over size and eccentricity? Christman, Kitterle, and Hellige (1991) reported data that shed some light on this question. They presented compound stimuli with two spatial frequency gratings superimposed on one another. In one condition the subjects' task was to determine whether or not a designated frequency (measured in cycles per degree, or cpd) was present. (We call the designated frequency a "medium" frequency since it was paired with a higher frequency in some cases and a lower frequency in others.) When the medium frequency (4 cpd) was present in the context of a higher frequency (9 cpd) grating, performance was better for LVF presentation; but when it was presented in the context of a lower fre-

quency (1 cpd) grating, performance was better in the RVF. Thus, a grating of the same frequency could show a right or left visual field advantage depending on whether it was the relatively high- or the relatively low-frequency component.

In a hierarchical pattern the global object contains lower frequencies relative to local objects independent of visual angle. Absolute frequencies vary with visual angle or stimulus acuity. The data from TPJ patients are consistent with the idea that the global/local hemispheric asymmetry may be a function of the analysis of *relative* spatial frequencies or spatial scale at the two levels of object structure (Ivy and Robertson, 1998).

A major question that arises from this discussion—how an absolute scale is converted to a relative one—is also a problem in object-based neglect. That is, how are absolute spatial attributes (whether locations or spatial scales) converted into relative ones? Conceivably, there is an early—perhaps preattentive—selection of a range of absolute values, a range that serves as input for subsequent analysis biased toward the higher or lower (or left or right) values it receives. Suppose, for instance, early mechanisms selected a frequency range of 1–4 cpd, then relayed this range to channels biased to attend to relatively higher frequencies (as purported for the left hemisphere). In that case, 4 cpd would be responded to more rapidly in the right than in the left visual field because it is the relatively higher frequency within that range. But what if the range selected were 4–9 cpd and that was relayed to secondary channels biased to attend to lower frequencies (as purported for the right hemisphere)? In that case, the 4-cpd grating—now the lower frequency within the range—would be responded to more rapidly in the left than right visual field. These are, in fact, the results observed by Christman, Kitterle, and Hellige (1991), and they are consistent with the global/local effects found in patients.

It is intriguing that recent imaging studies have found more activation of the right hemisphere when responding to global hierarchical patterns and more activation of the left hemisphere when responding to local patterns (Fink et al., 1996; Martinez et al., 1996). Although the exact locus is controversial (some reporting activation in the fusiform gyrus and others reporting activation near the temporal-parietal junction), asymmetry has been observed in posterior areas. ERP data also support a difference in the hemispheres over posterior leads with hierarchically structured letter patterns (Heinze et al., 1994; Proverbio, Minniti, and Zani, 1998), and the expected asymmetry has been observed in split-brain patients as well (Robertson, Lamb, and Zaidel, 1993).

One salient clinical fact is that hemispatial neglect is much more common, severe, and long-lasting after

lesions of the right than the left hemisphere. Since lesions of either the left or right TPJ may cause extinction (Vallar, 1993) or an extinction-like RT pattern, some other effect of right hemisphere lesions may account for the disparity in severity. The local bias produced by right TPJ lesions offers one explanation. Any factor that causes attention to become more actively engaged in the ipsilesional field will exacerbate the problem of disengaging attention, and thereby exacerbate visual neglect. In effect, the local bias engendered by right TPJ lesions causes patients to get “stuck” on local details. Since local details generally outnumber global ones, the difficulty in disengaging may be enhanced.

The conjoint effects of the local bias with difficulty in disengaging attention may contribute to some classic signs of neglect on paper-and-pencil tasks. Consider, for example, a patient writing numbers on a clock face. She will be more successful if, as she is writing in each number, she remains oriented to her task with reference to the whole clock. If her attention becomes focused on the number she is writing and she loses sight of the whole clock, she has difficulty in disengaging from that number to fill in the rest of the numbers on the clock face. On the other hand, if the clock face remains uncluttered with other numbers, patients with neglect are better able to remain oriented to the whole clock face. Di Pellegrino (1995) showed that patients with hemispatial neglect can put a single number in the appropriate location on a clock face provided they are given separate sheets for each number.

Halligan and Marshall (1994) asked a patient with left hemispatial neglect to bisect a horizontal line. In one condition they also presented a vertical line at the right end of the horizontal line. Before asking the patient to bisect the horizontal line, they gave the patient a task that required attending to the full extent of the vertical line, thereby obliging the patient to expand attention from the end of the horizontal line. The result was improved performance on the subsequent bisection of the horizontal line. By helping to overcome the tendency of the patient to become hyperengaged in a small focus of attention at the end of the line to be bisected, neglect was improved. Perhaps this expansion of attention to a more global level explains why patients with neglect make fewer errors when bisecting a rectangle than when bisecting a line—and why the higher the vertical extent of the rectangle, the less the bisection error (Vallar, 1994).

Objects and the loss of spatial orienting

Unilateral right parietal lobe lesions can produce hemispatial neglect in object-centered spatial coordinates (for

reviews see Rafal, 1998; Robertson, 1998). However, bilateral parietal damage produces different symptoms, collectively known as Balint’s syndrome (Balint, 1909; Rafal, 1997). Rather than neglecting both sides of objects, as might be expected if right and left neglect were summed, these patients see nothing but objects (figure 44.10; see also color plate 29). They can see just one object at a time (simultaneous agnosia), and the objects they see seem to appear automatically, only to be replaced randomly with other objects in the visual field. They have no difficulty recognizing faces, colors, single words, or shapes; but they exhibit severe spatial problems. They get lost. They cannot reach correctly; nor can they move their eyes toward a perceived object’s location or verbally identify its location as right, left, up, or down relative to themselves or to other objects. They can, however, correctly reach to locations on their own bodies and correctly move their right or left limbs upon command (Robertson et al., 1997).

As a result of these deficits, patients with this syndrome are extremely restricted in their everyday lives: They are spatially disoriented and require care with simple tasks such as eating, dressing, or moving around a room. In pure cases, they show few, if any, signs of aphasia, confusion, memory loss, or lack of judgment. They can be, in fact, cognitively normal except for the severe attentional and spatial deficits that render them functionally blind.

The syndrome is typically seen with bilateral damage in the inferior parietal lobes and adjacent occipital areas. Often, inferior regions of the superior parietal lobes are involved as well. In one patient, RM, whom we have been testing for several years, the lesions are centered in these areas (figure 44.11). The lesions damaged neither the optical fibers nor the primary visual areas, either anatomically or functionally.

Recent evidence suggests that a major underlying problem in these patients is the computation of or access to spatial representations that normally guide attention from one object to another in a cluttered field. It has been reported (Coslett and Saffran, 1991; Robertson et al., 1997) that such patients have difficulty searching for a conjunction target in a cluttered array. Any target that requires an attentional search from one object to another is impaired.

Patients with hemispatial neglect are also extremely slow to search for these types of target patterns, and the search time increases substantially as the number of distracters increases (Eglin et al., 1989). However, a single feature, such as a red dot among blue and yellow distracters, can be detected relatively rapidly in the hemineglected field and the speed of detection is not affected by the number of items in a display (Eglin et

FIGURE 44.10 (A) A patient with Balint's syndrome shown two superimposed objects. This gentleman reported seeing the comb; and when asked about the spoon, he reported he could not see it. These objects were then set aside for a few seconds. When the objects were picked up and presented to the patient again, he reported seeing only the spoon. After the objects were set down and shown a second time, the patient seemed perplexed and had difficulty deciding what he was seeing. When asked if he still saw either the comb or the spoon, he shook his head and said, "I think I see a blackboard with a

bunch of writing on it." In fact, there was a blackboard with writing in chalk in the background. (B) A second patient with Balint's syndrome, shown reaching for the handle of a screwdriver. Despite being able to report the object's identity and looking directly at it, he is not able to reach to its accurate location. When this patient was asked to reach for parts of his own body, he was able to do so easily and accurately, showing no evidence of a primary motor deficit or loss of coordination between an egocentric location and reaching.

al., 1989). Patients with Balint's syndrome are also able to detect features rapidly with few errors and are unaffected by the number of distracters in the display (Robertson et al., 1997). Normal subjects' response times to detect features are independent of the number of distracters as well (Treisman and Gelade, 1980).

Treisman and Gelade (1980) proposed that feature search does not require spatial attention while conjunction search does. The evidence from patients with Balint's syndrome and those with hemineglect supports this proposition. With lesions that affect spatial awareness, conjunction search is slow and limited, while

FIGURE 44.11 3D reconstruction of patient RM's MRI. The lesion locations are typical for patients with Balint's syndrome. Note that primary visual cortices and the temporoparietal junction are intact, which is consistent with RM's intact primary vi-

sual abilities as documented by formal ophthalmological examination (see Robertson et al., 1997). (Adapted from Friedman-Hill, Robertson, and Treisman, 1995.)

feature search in a similarly cluttered array remains relatively intact.

Electrophysiological, functional, and neuropsychological evidence has shown that primary features such as color, shape, motion, or size are represented more strongly in some areas of cortex (in different regions of posterior temporal lobes) than in others. To account for our perception of correctly conjoined features (e.g., a large green apple as opposed to large, green, and apple) in a cluttered array, we accept that some type of binding occurs. Otherwise, the features would remain separate or be miscombined, producing illusory conjunctions (Treisman and Schmidt, 1982). Treisman proposed that in order to correctly bind features together, spatial attention is required. In support of this theory, consider the patient with Balint's syndrome who perceived illusory conjunctions even when the stimuli were shown for up to 10 seconds in a two-item array (Friedman-Hill, Robertson, and Treisman, 1995; Robertson et al., 1997). Similarly, consider a patient with a unilateral left TPJ lesion who reported more illusory conjunctions in her contralesional field than in her ipsilesional field (Cohen and Rafal, 1991). These findings are consistent with difficulty in serial search—a

difficulty which, according to Treisman (1998), reflects a problem in binding the proper features of each item or group of items in a display due to problems in attending to locations.

Other evidence has shown that although these patients cannot explicitly access representations of spatial information in the external environment, their visual systems do contain some spatial maps. Robertson and colleagues (1997) asked patient RM to read, as rapidly as possible, the words UP or DOWN as they appeared on a computer screen. The word showed up in the upper or lower location of a surrounding rectangle and stayed on the screen until a response was made. When the word's meaning and location were consistent, RM responded 142 ms faster than when they were inconsistent. That is, he showed a spatial Stroop effect. But in accord with his spatial deficits, he had great difficulty in reporting whether the word was in the upper or lower portion of the rectangle: He said he was guessing, and his 51% correct performance was consistent with this report. He recovered some ability to explicitly access locations over time (85% correct), but his spatial Stroop effect did not change significantly (162 ms), demonstrating that the effect was not due to the degree of ex-

explicit spatial awareness. These data suggest the existence of multiple spatial maps—maps that contain information below the threshold of awareness. These maps may be tied to early visual input that normally feeds into the parietal lobes to create explicit spatial representations. And it is these representations that are used to guide attention in serial search or to other maps, possibly those associated with eye movements or reference frame selection (Robertson, 1998).

It is important to note that RM showed normal facilitation in an exogenous Posner cueing task with uninformative cues (Robert Egly, personal communication). Given the evidence for implicit spatial maps, this suggests that this type of attentional orienting, which is believed to be more automatic, does not require explicit spatial maps or, as seen in patients with extinction, even awareness of the signal evoking the orienting response (Danziger, Fendrich, and Rafal, 1998). RM also shows implicit effects on his response when looking for such things as letters within words, local forms within global forms, and semantic relationships.

It is clear that preattentive processing has a large effect on normal attentional orienting. Patients with neglect or extinction, and those with simultaneous agnosia as in Balint's syndrome, can tell us much about what features of objects and properties of displays of objects are preattentively processed and which require attention.

Visual attention may be summoned to a location reflexively by the midbrain extrageniculate system, by information in the visual scene that is a potential object, or by voluntary processes that guide strategic search from one location or object to another.

Concluding remarks

It is likely that the mammalian nervous system contains several different systems involved in selectively attending to objects and their locations. There is evidence that midbrain and several cortical regions contain spatial maps that can be used to control attentional orienting. Others appear linked to spatial coordinates that reside below awareness and may be more retinally or viewer based. Still others may be associated with spatial scale (i.e., global versus local). There appear to be many different areas of the brain that represent space either implicitly or explicitly, and in some cases other areas that control how attention is allocated within these representations (Rafal and Robertson, 1995). Deficits of attention may reflect direct insult to the control of attentional orienting; or they may reflect indirect insult arising from loss of underlying spatial representations that attentional systems require or from loss of object or feature information. The conse-

quences for the patient can be severe, resulting in limited access to information critical for some of the most basic functions of everyday life.

45 Spatial Reference Frames and Hemispatial Neglect

MARLENE BEHRMANN

ABSTRACT Acting upon an object requires not only an appreciation of its geometry and meaning, but knowledge of its spatial position as well. However, spatial position cannot be defined absolutely, so an object's location must be represented with respect to a coordinate system or spatial frame of reference. The question is: What coordinate system(s) are used for spatial representation, and what are the psychological and neural mechanisms involved in coding spatial position? To address these issues, evidence is obtained from studying the performance of neuropsychological subjects who, after lesions primarily affecting the right parietal lobe, manifest hemispatial neglect—a deficit in spatial representation. Interestingly, patients neglect contralateral left-sided information where left is defined with respect to multiple reference frames. Furthermore, the relative contribution of different reference frames may be weighted, and task requirements and contingencies may influence the use of various coordinate systems, and hence the manifestation of neglect.

A fundamental function of vision is to provide information such that objects can be acted upon. For example, reaching over to pick up a coffee cup requires not only that the visual scene be segmented into discrete objects, one of which is the cup, and that one appreciate the geometry of the cup and its handle, but also that the spatial location of the cup be adequately computed and represented. One of the most dramatic deficits in spatial perception and action is hemispatial neglect (“neglect” for short) in which a patient fails to orient toward or report information that appears on the contralateral side of space (see Driver and Mattingley, 1998, and Vallar, 1998, for recent reviews of this disorder). Neglect occurs more commonly and with greater severity after right- than left-hemisphere lesions, and the most frequent neural concomitant is the inferior parietal lobule (Bisiach and Vallar, 1988; Stone, Halligan, and Greenwood, 1993; Vallar, 1993). Because of this asymmetry, I will refer to neglect as being “left-sided.” Patients with neglect may not notice objects on the left of a scene, may ignore words on the left of a page or food on the left of a plate, and, typically, may fail to copy features on the left of a figure while preserving the corresponding features on the right, as shown in figure 45.1.

Neglect is not restricted to the visual domain: Patients may not orient to contralateral auditory information (Bisiach and Vallar, 1988; De Renzi, Gentilini, and Barbieri, 1989), may not detect a contralateral somatosensory stimulus (Làdavas et al., 1998; Moscovitch and Behrmann, 1994), and may even ignore contralateral odors (Bellas, Novelly, and Eskenazi, 1989; Bellas, et al., 1988). Neglect is also not restricted to sensory input: Patients with neglect may perform movements more poorly to the contralateral than ipsilateral side. This holds both for upper limb movements (Heilman, et al., 1987; Mattingley, Bradshaw, and Phillips, 1992; Mattingley and Driver, 1997; Mattingley, et al., 1998; Meador et al., 1986) and for eye movements (Gainotti, 1993; Girotti et al., 1983). Figure 45.2 shows the eye movements of a control subject and a neglect patient during visual search for the letter A embedded in a random array of letters, presented on a board spanning 45 degrees of visual angle horizontally. Each circle depicts the position of a single fixation in *x*- and *y*-coordinates and the size of the circle corresponds to the duration of the fixation. The normal subject searches roughly equally across the entire space; but the patient makes few eye movements into the contralateral space, and those that are made are extremely brief in duration (Behrmann et al., 1997). Interestingly, the patient makes many more fixations to the ipsilateral right side than does the normal control, and these fixations are long in duration. The poor lateralization to the left and increased attention to the right is consistent with many views of a gradient of attention across space from left to right (Behrmann et al., 1990; Kinsbourne, 1977; Mozer and Behrmann, 1990).

The failure to process information on the contralateral side can be attributed neither to a primary motor or sensory impairment nor to a hemianopia (Walker et al., 1991). Even when information is presented to the intact visual field of a neglect patient, information in the contralateral hemispace is still neglected (Làdavas, Petronio, and Umiltà, 1990). Patients may even show neglect in the absence of visual input; for example, patients ignore the left side of a scene constructed in visual mental imagery (Bisiach and Luzzatti, 1978) and fail to search the

FIGURE 45.1 Copy of a daisy and a clock drawn by two patients with left-sided neglect following a lesion to the middle cerebral artery of the right hemisphere.

left of a dark room (Hornak, 1992; Karnath and Fetter, 1995). Finally, patients can be cued to process information on the contralesional side (Mattingley, Bradshaw, and Bradshaw, 1994; Milner et al., 1993; Riddoch and Humphreys, 1983) through verbal or other visual instructions. Taken together, these findings rule out a primary sensory deficit as being causally linked to neglect.

Although considerable controversy remains concerning the exact underlying mechanisms that give rise to neglect, there is general agreement that these patients do not orient contralaterally of their own volition and thus fail to represent information on that side of space adequately (Bisiach, 1993; Bisiach, 1997; Driver and Mattingley, 1998; Halligan and Marshall, 1994; L  davas, Carletti, and Gori, 1994; McGlinchey-Berroth, 1997; Milner and Harvey, 1995; Vallar, 1998). In their comprehensive review of disorders of visual attention, Robertson and Rafal (chapter 44 in this volume) discuss neglect and other neuropsychological disorders of ori-

enting, the relationship between attention and eye movements, and the neural substrate that underlies various attentional deficits. The reader is referred to that chapter for more details on these issues. The focus of the present chapter is rather more restricted, centering on the question of the nature of the spatial representations in parietal cortex.

The specific question to be addressed is this: When the patients ignore information on the left, what is it left of? Because "left" and "right" cannot be defined in absolute terms, they must always be qualified with respect to a set of coordinates or spatial reference frame—i.e., relative to an origin and axes. It is these spatial coordinates that are used for organizing spatial information, and for establishing spatial relationships between objects in the scene and between the observer and the objects. By examining what determines the midline such that information to the left of it is neglected, we may understand how spatial position is coded in parietal cortex.

Spatial reference frames coding left and right (horizontal)

A number of potential reference frames can be used to define and code left/right positions in space (Feldman, 1985; Hinton, 1981). These can be divided into two broad classes: Objects and locations can be defined relative to the viewer's vantage point (*egocentrically*), or they can be defined *allocentrically* from an extrinsic vantage point independent of the viewer's position. If positions were coded egocentrically, patients with left neglect would ignore information to the left of the viewer's midline. If positions were represented in allocentric coordinates, patients with neglect would ignore information to the left

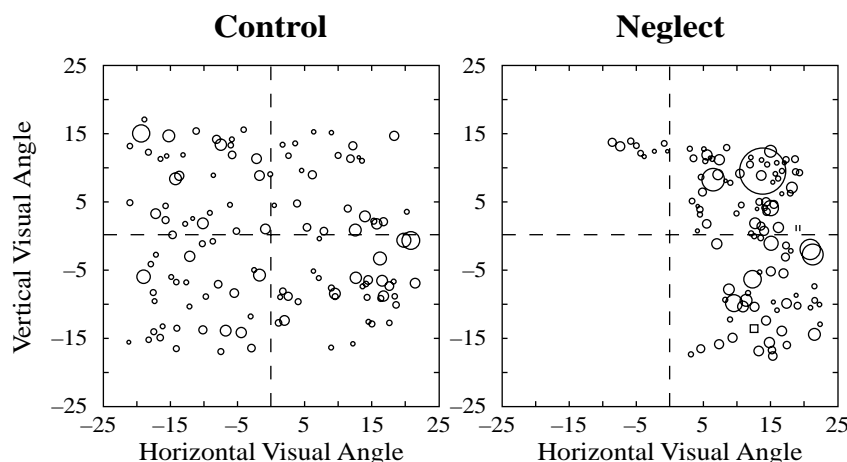

FIGURE 45.2 The location (in x - and y -coordinates) and duration (reflected as size of the circle) of fixations for a normal control subject and a typical patient with hemispatial neglect during search for the letter A in a random array of letters covering ap-

proximately 45 degrees of horizontal visual angle. Subjects wore a scleral contact annulus in one eye while they viewed the target display. Eye position was sampled every 5 ms (i.e., 200 samples per second). (Adapted from Behrmann et al., 1997)

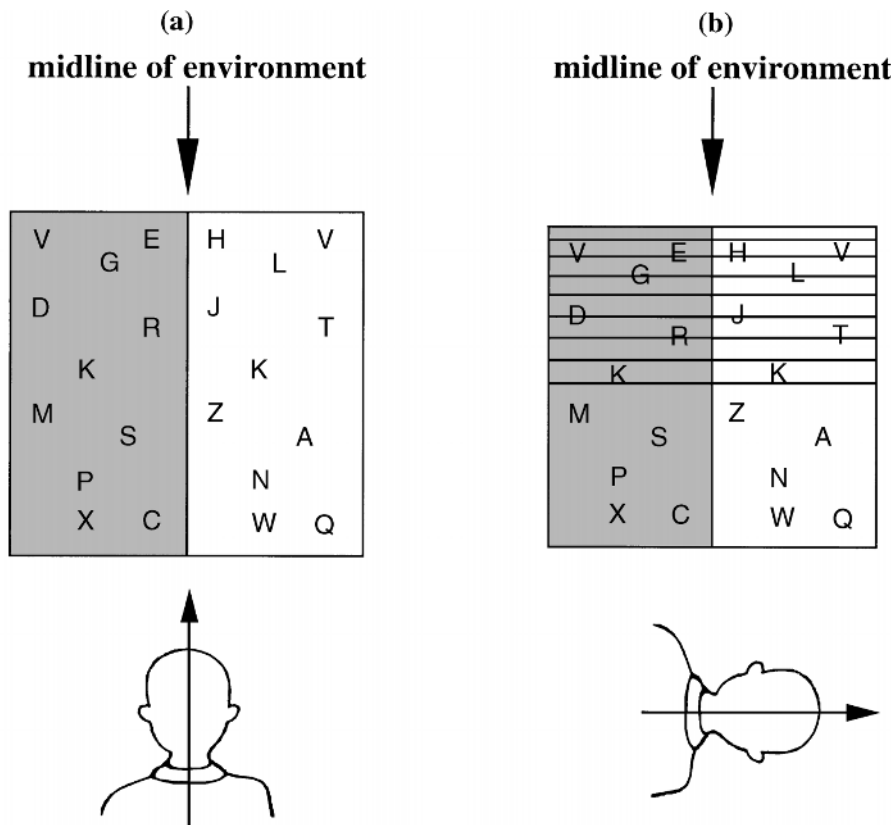

FIGURE 45.3 Left-sided neglect in environment- and viewer-based frames. Neglect patients report fewer letters from the shaded region in the panel (a). They report fewer letters from

the shaded region in the panel (b), that is, the left of the environment frame, but also fewer letters from the striped region, i.e., the left of the viewer's midline (viewer frame).

of the midline of the environment or scene, or perhaps even to the left of individual objects present in the scene. There are, however, a number of potential reference frames that may be identified within the categories of allocentric and egocentric reference frames. But before examining the evidence for these more specific reference frames, data supporting the initial distinction between the broad classes are presented first.

To determine whether spatial position is defined egocentrically and/or allocentrically, several studies have examined whether the neglected information falls to the left of the midline of the viewer or of the environment. In such studies patients typically perform a task such as simple target detection (e.g., Gazzaniga and Lâdavas, 1987; Lâdavas, 1987) or reporting of words, letters, colors, or objects (e.g., Behrmann and Moscovitch, 1994; Calvanio, Petrone, and Levine, 1987; Farah et al., 1990). The tasks are generally performed in two different conditions. In the first condition (figure 45.3a), subjects are seated upright, with the midsagittal plane of the trunk, eyes, and head aligned with the midline of the display (scene) or environment. Under this condition, however, the left of the viewer is confounded with the left of the environment (or gravitational upright), and hence it is not possible to de-

termine which spatial reference frame determines what information is neglected. The second condition (figure 45.3b), in which the two frames are dissociated, is critical to deconfound the two reference frames. In this condition, the patient rotates his/her head and/or body in the frontal plane, orthogonal to gravity. Under this arrangement, the left of the viewer maps onto the upper region of the display, but the left of the environment remains as if the viewer were physically upright; thus, one can evaluate the amount of neglect in the viewer and environment reference frames separately.

Findings from most of these studies support the existence of both egocentric and allocentric neglect; even when the midline of the viewer is rotated away from that of the environment, patients report information on the left more poorly than that on the right defined with respect to the upright environment. Importantly, performance is also poorer for information presented to the left than to the right of the viewer's midline. In fact, in the single quadrant that is on the left in both of these frames, performance is poorest (Calvanio, Petrone, and Levine, 1987), as depicted in figure 45.3b (upper left quadrant). These results suggest that neglect may manifest in both egocentric and allocentric reference frames

simultaneously. Whether each individual reference frame contributes additively (as a vector sum, for example) or multiplicatively on each trial, or whether one dominates in some trials but not in others, remains to be determined. (For some interesting ideas and simulations using a basis function model, see Pouget and Sejnowski, 1997a,b.) The more specific question concerning the relative contribution of spatial reference frames within each of these two broad classes is considered next.

EGOCENTRIC REFERENCE FRAMES Within an egocentric frame of reference, left is defined with respect to the viewer's own body coordinates. At least four different egocentric frames may be identified, however: "Left" may be defined with respect to the midline of (1) the eyes or vertical meridian of the visual field, (2) the head, (3) the trunk, or (4) the longitudinal axis of the limb involved in executing an action, such as the arm.

Experiments that examine the individual contribution of a single egocentric reference frame adopt the same logic as experiments that differentiate between egocentric and allocentric neglect by rotating one reference frame out of alignment from the other. For example, to examine the individual contribution of a reference frame centered on the eyes, Kooistra and Heilman (1989) compared the visual fields of a single patient in two conditions: (1) when the eyes, head, and trunk all coincided; (2) when the head and trunk were held in the midsagittal plane but the eyes deviated 30 degrees to either the left or right. The critical finding was that the patient failed to detect the stimuli when her gaze was straight ahead or when her gaze deviated to the left; but the patient performed well when her gaze deviated to the right, indicating some amelioration of the neglect with the eyes deviated to the right. We, too, observed a modulation of neglect when we recorded the latency and accuracy of saccades in neglect patients performing a detection task in which targets were presented at 5, 10, or 15 degrees to the left or right of the midline of the eye or retinal axis. When the eyes are pointed straight ahead (0 degrees), the targets fall along a gradient with best detection and latency on the right and poorest on the left. Latency (and also accuracy to some extent) was modulated by position of the eye in the head. When the eyes were deviated 15 degrees to the right, neglect was significantly ameliorated; but there was no real change in detection when the eyes were deviated 15 degrees to the left (Behrmann et al., 1999). Modulation of neglect by the line-of-sight (or orbital position) has also been shown by Bisiach, Capitani, and Porta (1985) in a tactile exploration study and by Duhamel and colleagues (1992), although in this latter study this was so only under certain testing conditions (see also Hillis et al., 1998).

Although these findings suggest that the retinocentric and/or oculocentric axis plays some role in determining what is neglected (see also the section below on related findings from single-unit studies with nonhuman primates), it is unclear whether these are the only egocentric reference frames that are important or whether others might also contribute. Karnath and colleagues, for example, have argued that the midline of the trunk (body-centered reference frame) plays a fundamental (perhaps exclusive) role and serves as the anchor or midline for dividing space into left and right (Karnath, Christ, and Hartje, 1993; Karnath, Fetter, and Dichgans, 1996; Karnath, Schenkel, and Fisher, 1991). In their experiments, subjects performed a target detection task with the eyes, head, and trunk all aligned in the midsagittal plane (baseline) or with either the head or the trunk rotated by 15 degrees. Targets were presented at 7 degrees to the left or right and saccadic latency was measured. Interestingly, there was no difference in RTs between the baseline condition and either condition involving the rotation of the head. There was, however, significant amelioration of neglect when the trunk was rotated to the left compared to the baseline condition. Surprisingly, however, the neglect was not exacerbated by trunk rotations to the right—a result they acknowledge as puzzling. [See also Karnath (1997) for further discussion and consideration of vestibular and optokinetic variables, and Farnè, Ponti, and Lâdavvas (1998) for a more general evaluation of these findings.] Support for the role of the midline of the trunk is also obtained from a study by Beschin and colleagues (1997), who found a decrease in neglect when the visual display was placed to the right of the trunk but not when it was placed to the right of the head or eyes (although the testing conditions are not perfectly comparable in this experiment). Unfortunately, this study cannot shed light on the possible increase of neglect with the display placed to the left of the trunk as this condition was not tested. It appears, however, that, under certain conditions, neglect can be ameliorated by leftward rotations of the trunk midline and exacerbated by rightward rotations of the trunk midline (Chokron and Imbert, 1993).

But the body midline cannot be the only bisector of space into left and right, as neglect can be observed for information placed solely to the right of the body midline (Lâdavvas, 1987). Furthermore, some studies have shown that the extent of the deviation error produced by neglect patients in a line bisection task remains the same irrespective of whether the lines to be bisected are placed to the right or left of the trunk's midline (Ishiai, Furukawa, and Tsukagoshi, 1989; Reuter-Lorenz and Posner, 1990). In addition, Morris Moscovitch and I showed that even when the right hand remained on the

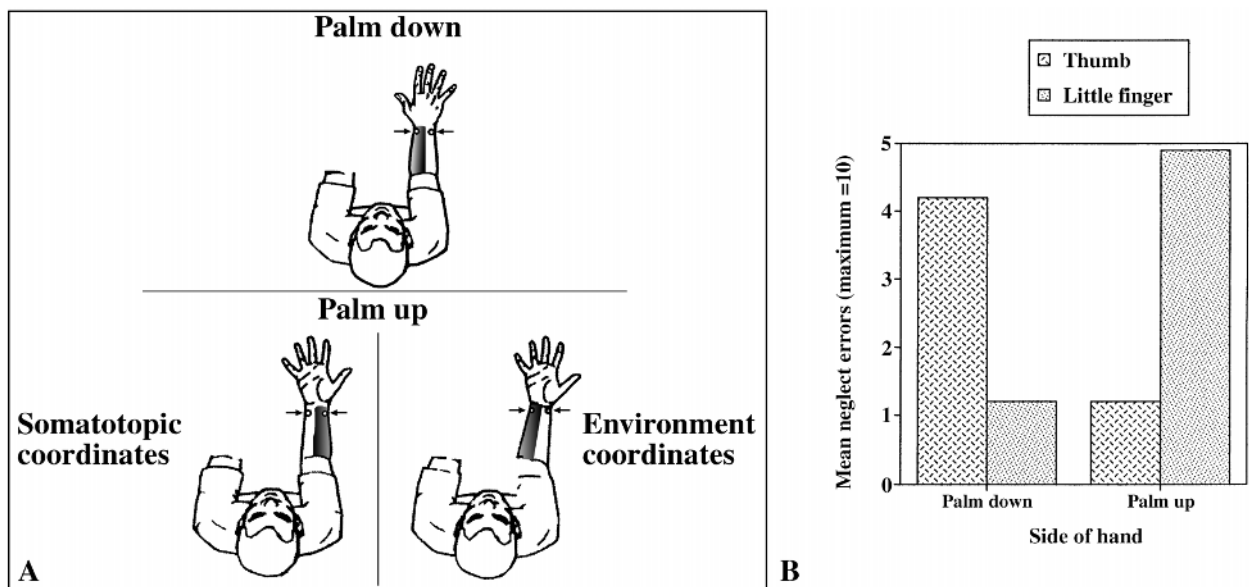

FIGURE 45.4 (A) Depiction of testing conditions of tactile neglect and (B) results showing mean number of errors in tactile detection for targets on the thumb and little finger side in the

right of the body midline, tactile neglect was still observed. We designed this last study with two goals in mind: to examine whether tactile neglect could be observed in patients with visual neglect and, if so, to determine the frame of reference of tactile neglect. Using blindfolded patients with visual neglect, we applied a light tactile stimulus to the intact ipsilateral right hand on the thumb and/or little finger side, then directed the patients simply to indicate the location of the tactile stimulation (Moscovitch and Behrmann, 1994). All the patients reported fewer stimuli from the left side of the wrist (toward the thumb) than from the right (toward the little finger) while the hand was palm-down, as shown in figure 45.4 (these data are only from the bilateral simultaneous stimulation condition). When the hand was turned palm-up, the patients neglected the stimulation on the little finger side more than that on the thumb side. These findings indicate that tactile neglect does occur in patients with visual neglect, supporting the view that there is a common or unitary spatial map accessible by more than one sensory modality. More relevant for this discussion, however, is the finding that it is not the somatotopic surface that determines the spatial position of tactile stimuli (i.e., the patients do not always neglect the thumb side); rather, a more abstract, allocentric reference frame— independent of limb orientation—is used for representing the locations of stimuli and for coding what is on the “left.” Importantly, it is also not the midline of the body that determines the neglect, as the same result occurs when the hand is right of the body midline.

palm-down and palm-up position when stimuli are delivered to both sides simultaneously. (Adapted from Moscovitch and Behrmann, 1994.)

Rather less research has been done to evaluate the role of the position of the limb on neglect performance. In their tactile exploration study, Bisiach, Capitani, and Porta (1985) manipulated not only eye position but also the placement of the right limb. In two conditions, the workspace of the limb fell along the midline of the trunk; and in the remaining two, the limb extended into the right side of space (as the board to be explored tactually was placed to the right). Performance did not differ in these conditions, suggesting that the limb coordinates are not crucial in affecting neglect (but see Graziano and Gross, 1996, for discussion of how the limb coordinates influence the neuronal activity of putamen and premotor neurons in monkeys). A recent study, however, suggests that there may be some involvement of limb coordinates, although this may primarily involve the spatial position of the limbs in relation to each other. In this study, Aglioti, Smania, and Peru (1999) applied bilateral stimulation to the dorsum of the hands when the hands were either placed straight ahead (anatomical position) or crossed one over the other. When the hands were crossed, the crossing could occur across the midline of the body or just in the right or in the left hemisphere. The extinction of the stimulus on the left hand was prevalent in the anatomical position. But in the crossed position, there was both improved detection of the stimulus delivered to the left hand and poorer detection of the right-hand stimulus—and this was the case irrespective of whether the hands were positioned on the left, on the right, or across the midline of the trunk. These findings suggest that spatial

position of a tactile stimulus to one hand is coded with some sensitivity to the location of the other limb, and that this is independent of the midsagittal plane of the trunk.

Evidence supporting the contribution of the final egocentric frame, one defined with respect to the midline of the head, is still somewhat controversial. For example, although Karnath, Christ, and Hartje (1993) found no modulation of neglect with changes in head orientation, we have found that the neglect pattern is influenced directly by the position of the head on the trunk, albeit to a lesser extent than some other reference frames (Behrmann et al., 1999; note, however, that the combined influence of target defined retinally and by orbital position codes position with respect to the head). It is also useful to note that in those studies that differentiate egocentric from allocentric coordinates and in which the patient's head (but not body) is tilted to the right or left, neglect may be occurring with respect to the midline of the head (as in figure 45.3). In these paradigms, however, it is not clear whether the neglect is indeed head-centered because the observed neglect may be defined by the position of the eyes or of the head as both are rotated from upright in the frontal plane (see also Hillis et al., 1998).

The studies reviewed thus far clearly point out the modulation of the severity of the neglect as a function of the midline of the trunk, the gaze angle or line-of-sight, and the position of the limb and perhaps, albeit to a lesser extent, the midline of the head. Whether or not these various egocentric frames are truly separable from each other, and hence independent, or whether they are contingent on each other to various degrees remains to be determined.

ALLOCENTRIC REFERENCE FRAMES Just as a number of different reference frames can be defined egocentrically, and can influence performance differentially, so too can different allocentric reference frames be identified and evaluated. The two main allocentric frames include one defined with respect to the midline of a visual scene or environment, and one defined with respect to the midline of individual objects or perceptual units in the scene.

The derivation of an environment-centered frame requires computations involving gravitational forces on the otolith organ of the vestibular system, visual input to define environmental landmarks with respect to gravity, and proprioceptive and tactile information to provide a sense of the body's posture in relation to gravity. As suggested earlier on, several studies have observed that the midline of the environment is important in separating out the left and right of space, as evident from the neglect of the left of the upright environment when the

viewer is tilted (Behrmann and Moscovitch, 1994; Calvanio, Petrone, and Levine, 1987; Farah et al., 1990; Ládavas, 1987). Mennemeier, Chatterjee, and Heilman (1994), however, have argued that the environmental frame is perhaps the most important, and even more salient than a viewer-based frame. Their conclusion is based on a line bisection study with two patients with multidimensional neglect, in which the environmental and body-centered frames were brought into opposition through rotating the subjects' body in left, right, prone, and supine positions. The critical finding was that the patients' bisection errors were predicted better by the environmental than body-centered frames, leading the researchers to conclude that environment coordinates dominate in coding spatial positions.

There is, however, another interpretation of the data invoking the centrality of the environment-based frame, and that concerns the role of gravity. Because visual information was present in all of the studies described above, it is possible that visual, rather than gravitational, information may have played an important role. Thus, when subjects were required to search for a spot of light in the dark with their bodies either upright or tilted to the left or right, forward or backward, subjects exhibited a bias to search the ipsilesional hemispace for this visual stimulus—and this bias held equivalently across the different body rotations. These findings suggest that it is the body midline (and translating the visual information in relation to this midline) rather than a gravity-based environmental display that may potentially underlie the previously reported environment-based neglect (Karnath, Fetter, and Niemeier, 1996).

In the last few years, considerable evidence has accumulated suggesting that spatial position may be coded with respect to another allocentric frame, the midline of an individual object, and that patients neglect the left side of an individual object regardless of its spatial position. Gainotti, Messerli, and Tissot (1972) first observed that, in copying several objects in a scene, some patients failed to copy the left side of an individual object while still copying objects located further to the left of their own incomplete drawings (see also Caramazza and Hillis, 1990; Halligan and Marshall, 1993, for examples). A problem with interpreting this provocative result, however, is that copying is a sequential task. Thus, when a subject copies a single element in a display, that element becomes the entire scene or environment and the subject may neglect information on its left. When the subject moves to copy the next element, this next element then becomes the entire environment and the left of this next object is neglected. Under these conditions, one cannot easily distinguish between object- and environment-based neglect.

Object-based neglect, however, has now been observed in a number of studies using very different paradigms. In one of the first studies to address this issue, Driver and Halligan (1991) asked their patient, PP, to make same-different judgments on two upright, elongated nonsense shapes placed one above the other in the midline of the viewer. Of most relevance is the fact that PP failed to detect the point of difference when it fell on the left under these conditions. Even more dramatic was the finding that the point of difference was still not detected when, for example, the two shapes were rotated 45 degrees to the right and the point of difference fell on the right of the viewer but on the left of the object defined by a longitudinal axis through the midline of the object. This demonstration of object-based neglect is consistent with the report of Caramazza and Hillis (1990) who showed that their patient, NG (who had right-sided neglect after a left hemisphere lesion), failed to read the letters on the right of a word, irrespective of whether the word was written in standard format, was printed vertically, or appeared in mirror-reverse format.

Along the same lines, Young, Hellawell, and Welch (1991) showed that their patient, BQ, neglected the left side of chimeric stimuli (in which the left side of one object is joined to the right side of a second object). Particularly impressive is the fact that BQ reported the identity of the face on the right side of the chimeric stimulus more accurately than the left both when the chimeric stimulus was presented upright in the intact ipsilesional field and when the chimeric stimulus was inverted 180 degrees so the right half of the upright face fell on the left side of space. (But performance was not perfect in this condition, reflecting the fact that this right side of the face was on the left of some other coordinate frame.) The failure to orient toward and process the left half of the chimera is also evident in eye movements; Walker and colleagues (1996) reported that their patient, RR, restricted his fixations to the right side of an individual object. This object-based pattern could not be attributed to the failure to fixate the left of a display, as RR could scan both the left and right of scenes and could also make left saccades when the left half of an object was presented in his left visual field (Walker and Findlay, 1997; Walker et al., 1996). A host of other studies now support these results which, taken together, suggest that the boundaries and properties of an individual object in a scene may play an important role in defining what is "left."

To examine the contribution of a reference frame centered on an individual object, Steve Tipper and I devised an experiment (influenced by some of his previous work with normal subjects on inhibition of re-

turn in object coordinates) in which we could systematically disambiguate the object-based frame from other confounding reference frames. In these studies, we presented neglect patients with computer displays consisting of an object (barbell) in which the two circles were colored differently (see figure 45.5). The barbell appeared in the center of the computer screen (or entirely on the right for patients with a left field defect); then, after a short delay, on two-thirds of the trials, a target or probe in the form of a small white dot appeared in the center of either the left or the right circle. The patients pressed a key as soon as they detected the presence of this target, and we measured their accuracy and speed. As expected, in this "static" condition, patients took much longer or made more errors in detecting the left than the right target. Because the left and right of the barbell are aligned with other reference frames, a decoupling condition was introduced. In this second, "rotating" or moving condition, the midline of the barbell is dissociated from various other reference frames in the following way. First the barbell is presented on the computer screen; then after a short delay, it is rotated 180 degrees around the midpoint of the connecting horizontal rod while the patients watch. When the rotation is complete and the barbell has reached its stationary position, a short delay ensues, whereupon the target appears on the left or right of space. Note that, as shown in the example in figure 45.5, the display in which the target is presented is identical in the static and rotating condition. However, in the rotation condition, the original left circle of the barbell is now on the right side on the computer screen and the original right circle is now on the left side of the screen. This arrangement allows us to determine whether the patients now neglect targets appearing on the "good" right side of space (but on the left of the object) and show good detection of targets appearing on the "poor" left side of space (but on the right of the object).

As is evident from the lighter bars in the graph in figure 45.5, patients are significantly slower to detect left- than right-sided targets in the static condition. The situation is reversed in the rotating condition: Now, patients are faster at detecting the left- than right-sided target, as shown by the darker bars. The explanation that we proposed for this paradoxical reversal of neglect was that patients neglect the information that falls to the left of the object's midline and, conversely, attend well to the information that falls to the object's right. Even when the object moves into a new spatial location or undergoes a complete rotation, information on its left is still at a disadvantage compared to information on its right. This pattern cannot be attributed to an artifact of eye movement; even when eye movement is controlled, the same pattern

A

FIGURE 45.5 (A) Depiction of the static and rotating conditions with identical final displays. One circle of the barbell was colored red and one colored blue. (B) Mean reaction time for 4 patients with neglect to detect the target on the left and right in the static and moving conditions. Note that, because the fifth

is observed (Tipper and Behrmann, 1996). Nor is this finding obviously attributable to the covert tracking of the left or right of the object. In fact, relative to the static condition, in the moving condition, the facilitation for targets on the left together with the inhibition of targets on the right critically depends on the two circles' forming a unified object—it is not evident when the two circles are not joined. If the result were simply a function of the patients' covertly tracking, say, the right circle of the barbell (to which their attention is drawn initially), a similar finding should be obtained even when the two circles are not connected. These findings led us to conclude that spatial positions are also defined with respect to an object-based reference frame and hence information to the left of this frame may be neglected.

To examine whether neglect can arise for information defined in multiple coordinates simultaneously (one of which is object-based), we extended this experiment by adding to the barbell display two gray squares (Behrmann and Tipper, 1999). These squares served as stationary markers—they remained fixed to the left and right sides of a second reference frame defined with respect to either the environmental or viewer midline (for short, we refer to this as “location-based”) even on trials when the barbell rotated (see figure 45.6A). In this experiment, when the target appeared, it did so with equal probability in the left or right of the barbell or in the left or right square. Trials that probed these four target positions were randomly ordered so that the patients could not predict where the target would appear.

B

subject made so many errors, his data are not included here in the RT analysis; however, his data reveal the same pattern with accuracy as the dependent measure. (Adapted from Behrmann and Tipper, 1994.)

Importantly, as shown in figure 45.6B, the finding of object-based neglect was replicated: Performance was poorer for targets on the left than on the right of the barbell in the static condition, and this was reversed in the moving condition (left panel of graph showing only the data from the barbell). The novel finding, illustrated in the right panel of figure 45.6B, was this: When the target appeared in the left square, detection was always slower than when the target appeared in the right square, irrespective of whether the barbell remained static or rotated.

In a final experiment in this series, we added one further manipulation: Whereas the targets appeared equi-probably on the left or right of the barbell or squares in the previous experiment, we included two additional blocks of trials with the same subjects. In one of these blocks, the proportion of targets that would appear in the object-based frame or the location-based frame was either 20% or 80%, respectively, or the converse in the second block. The results from these additional blocks indicated that, as the probability of a target's appearing in the barbell was increased, so the severity of object-based neglect increased, reflected as a larger reversal of neglect in the static and moving conditions. Taken together, these results suggest two important conclusions. First, patients can neglect the left of the environment and/or viewer frame and, at the very same time, can neglect the left of an object, even when the left of the object is on the right side of space (as demonstrated by the rotating barbell). Second, the distribution of visuospatial attention in

neglect to detect the target on the left and right in the static and moving conditions in the two different reference frames. (Adapted from Behrmann and Tipper, 1999.)

these two frames of reference is flexible, and may be influenced by task demands or contingencies (see also Hillis, Mordkoff, and Caramazza, in press). These findings suggest that the parietal lobe can code spatial information relative to multiple spatial reference frames simultaneously and flexibly.

Almost all of the studies demonstrating object-based neglect discussed thus far might arguably require some form of mental rotation. Indeed, it has been suggested that there is no such phenomenon as object-based neglect, and hence that all these results could be accounted for by mental rotation. If patients mentally rotated images to the canonical upright before the left and right were coded, and if there were a gradient of attention across space (Kinsbourne, 1987; Mozer and Behrmann, 1990), then the left of an object would always be disadvantaged relative to its right. Indeed, Buxbaum and colleagues (1996) have shown that it is only when the patient is instructed to use mental rotation that the object-based neglect emerges. This explanation, however, is still somewhat controversial for two reasons. First, in none of the studies on object-based neglect reported thus far are the subjects instructed to use mental rotation; yet the neglect for the left of the object was still observed (whereas the effect was observed only when the patient was instructed to use mental rotation in Buxbaum et al., 1996). Second, whether or not these patients can actually make use of mental rotation is also unclear, given that the right parietal cortex (which is damaged in these patients) plays a critical role in mental rotation (Alivasatos and Petrides, 1997) and lesions to it usually impair the ability to perform mental rotation (Farah and Hammond, 1988; Ratcliff, 1979).

There are, moreover, several elegant studies of object-based neglect in which mental rotation is clearly not required. For example, Driver and colleagues showed that a neglect patient failed to detect a small gap that appeared on one side of a triangle (Driver et al., 1994). This was only the case, however, when, the gap fell to the left of the midline of the triangle, and the orientation of the triangle was biased by virtue of surrounding triangles. (See also Reuter-Lorenz, Drain, and Hardy-Morais, 1996, for results with normal subjects showing directionally specific object-based processing.) Several other studies have also shown that perceptual organization or grouping processes can significantly influence the manifestation of neglect and perhaps even reverse it (Driver, Baylis, and Rafal, 1992; Grabowecky, Robertson, and Treisman, 1993; Humphreys and Riddoch, 1995; Riddoch et al., 1995). Recently, for example, Ward, Goodrich, and Driver, (1994) showed that when the contralesional item could be grouped with the ipsilesional information on the basis of Gestalt factors such as

similarity (for example, a bracket on the left and a bracket on the right) or symmetry, report of the left-sided stimulus improved by roughly 50% compared to when the left-sided information could not be grouped with a simultaneous right-sided stimulus. The same pattern was obtained when the two items formed a familiar configuration (for example, an arrow made of a left arrowhead and a right horizontal bar). Similar effects of grouping have been observed with normal subjects in which unattended information is processed better if it forms part of an object defined by uniform connectedness (see, for example, Kramer and Hahn, 1996; Watson and Kramer, 1997).

This amelioration of neglect through grouping has now been replicated in several studies, and better processing of the contralesional information has been shown when the left-sided information can be grouped with corresponding right-sided information by bottom-up factors such as color and proximity (Driver and Haligan, 1991) or brightness, or by the presence of collinear edges (Gilchrist, Humphreys, and Riddoch, 1996; Rorden et al., 1997). Information on the left may also be grouped with the information on the right (and hence preserved) by a global outline (Driver, Baylis, and Rafal, 1992; Farah, Wallace, and Vecera, 1993), by an illusory contour (Kanizsa-type figure) of a partially occluded figure (Mattingley, David, and Driver, 1997), or by any well-configured object or whole (Gilchrist et al., 1996; Humphreys and Riddoch, 1994). One possible mechanism for determining what constitutes an object is a computation of the center of mass of the display. Two recent studies (Grabowecky et al., 1993; Pavlovskaya, et al., 1997) suggest that this might be the case (Robertson and Rafal, chapter 44 in this volume, discuss this in more detail). Both Grabowecky and Pavlovskaya manipulated the center of mass of the stimulus, either by adding features to one or both sides of a central set of features or by altering the luminance of the display. In both cases, patients neglected more information on the contralateral side if the center of mass was shifted rightward, suggesting that a coarse (perhaps preattentive) description of the display provides a basis for further spatial computation.

However, perceptual features are not the only basis on which "objectness" is determined, as semantic cohesiveness can also ameliorate some left-sided neglect. For example, Behrmann and colleagues (1990) showed that patients who failed to read the word COW correctly when presented to the left were able to read it better when the word BOY was presented simultaneously on its right, as in COWBOY—and some advantage was obtained even with a blank space between the two component words, as in COW BOY. The advantage from the

right-sided context was observed only when the two words (COW BOY) constituted a real compound word rather than a noncompound item such as COW SUN (see Mozer and Behrmann, 1990, for a computational implementation and explanation of this behavior).

These findings suggest a couple of factors: Both perceptual and more conceptual object properties play a role in determining what is neglected. Information to the left of the midline of an object may be neglected, but this neglect may be offset if the information to the left coheres well with the corresponding right-sided information. Preattentive processes may suffice to bind the left- and right-sided information together in many cases, but top-down factors like semantic or morphological composition may also modulate the distribution of attention (Mozer and Behrmann, 1990).

Spatial reference frames coding up/down and near/far

Thus far, this chapter has focused exclusively on reference frames coding left and right. But similar questions apply with regard to other spatial dimensions, such as up/down (vertical) and near/far (radial). It would be remiss not to include a brief discussion of spatial coding in other dimensions, as patients with parietal lesions show impairments in representing locations in these other planes as well. For example, some patients show “altitudinal neglect,” in which they omit more information from the upper than lower portion of the array (Shelton, Bowers, and Heilman, 1990) or vice versa (Butter et al., 1989; Halligan and Marshall, 1989; Mennemeier et al., 1994; Nichelli et al., 1993; Pitzalis, Spinelli, and Zoccolotti, 1997). Performance may also differ along the radial dimension. Some patients show only personal neglect, in which, for example, they fail to brush their hair, shave their faces, or apply makeup on the left (Beschin and Robertson, 1997; Guariglia and Antonucci, 1992; Peru and Pinna, 1997). Other patients show only peripersonal, but not personal, neglect; in this case, they ignore contralateral information presented near but not on the body (Halligan and Marshall, 1991; Mennemeier, Wertman, and Heilman, 1992). Other patients ignore only contralateral information presented in far or extrapersonal space (Bisiach et al., 1986; Cowey, Small, and Ellis, 1994). Interestingly, it may be that neglect along the near–far axis is apparent only when the subject must produce a motor response to the stimulus and not when spatial perception alone is tested (Pizzamiglio et al., 1989). The fact that neglect can be dissociated for various distances suggests that the parietal cortex also incorporates information about the proximal–distal plane (Rizzolatti and Berti, 1990).

CORRESPONDING DATA FROM NONHUMAN PRIMATES The data obtained from human subjects with hemispatial neglect suggest that there are a number of different reference frames computed by parietal cortex. Whether these different representations are subserved by a single neural region within parietal cortex or whether there are distinct neural substrates is not easily answered in the context of human studies, given that the lesions (usually resulting from a middle cerebral artery infarction) are generally large and multiple parietal regions are implicated. Animal studies, therefore, provide an important source of converging evidence on the issue of spatial representation. There is no direct analog of hemispatial neglect in monkeys, and anatomical and cytoarchitectonic homologies between posterior parietal cortex in monkeys and humans are hardly perfect (Crowne and Mah, 1998); nevertheless, several experimenters have described the occurrence of visual extinction after lesions to the posterior parietal areas (Gaffan and Hornak, 1997; Lynch and McLaren, 1989; Rizzolatti, Gentilucci, and Mattelli, 1985). Perhaps more informative for the current purpose are the findings from single-neuron recording studies conducted in the parietal cortex of awake, behaving monkeys. Results of these studies are reviewed here briefly; for further details, the reader is encouraged to consult the many excellent papers by Andersen and colleagues (Andersen et al., 1997, 1993) and by Colby and colleagues (Colby, 1996, 1998; Colby and Goldberg, 1999).

The work with monkeys has provided direct evidence that parietal cortex contains several distinct areas and multiple representations of space. Within the class of egocentric representations, neurons in the lateral intraparietal area have receptive fields that map targets relative to the retina, and the activity of these neurons can be significantly modulated by orbital position (Andersen, Essick, and Siegel, 1985). Interestingly, these neurons can also update their retinal image in conjunction with an eye movement so that their internal representation always matches the current eye position (referred to as an eye-centered representation; Colby, Duhamel, and Goldberg, 1993; Duhamel, Colby, and Goldberg, 1992). Neurons that code stimulus location relative to the head have also been described, this time in the ventral intraparietal sulcus (Brothie et al., 1995). These neurons can be driven by both visual and somatosensory stimulation, and the tactile and visual receptive fields are in close correspondence.

Directional selectivity of neurons is also evident when monkeys make movements of similar direction but to different parts of the workspace (Caminiti et al., 1991), and neurons in premotor cortex have receptive fields that

FIGURE 45.7 Histograms of the average firing rate of a single neuron over time showing the directional selectivity for a position on the left of a bar, irrespective of the physical direction of

move with the arm (Graziano, Yap, and Gross, 1994). Neurons in the medial intraparietal area are specialized for responding to stimuli within reaching distance (Colby and Duhamel, 1991) and likely play an important role in deriving arm- and reaching-related spatial representations. Finally, results that converge with the object-based neuropsychological findings have been obtained from recordings of single neurons in monkeys required to move their eyes to the left or right of objects (Olson and Gettner, 1995; Olson, Gettner, and Tremblay, 1998). Interestingly, the results showed that neurons in the supplementary eye field—a premotor area in frontal cortex—are activated selectively when the monkey is planning to make an eye movement to the left of an object, whereas other neurons are activated when the monkey plans an eye movement to the right of an object (see figure 45.7). This object-based directional selectivity occurs regardless of the direction of the eye movement required and the retinal position of the object, regardless of the exact visual features of the object, and regardless of whether the monkey was specifically following an object-centered instruction. These results point directly to a neural mechanism that might be responsible for locating positions in an object-based reference frame. Damage to neurons with object-left spatial selectivity would then give rise to the object-based neglect that is revealed by the patients.

Outstanding questions

Many unanswered questions concerning the frames of reference for coding spatial position remain. Whether or not egocentric and allocentric frames (and the many different frames within each of these categories) are independent of each other in humans remains to be determined. For example, Farah and colleagues (1990) have suggested that in their sample, viewer-centered and environment-centered neglect always co-occurred but there was no evidence of

the movement (right or left in the orbit). (Adapted from Olson and Gettner, 1995.)

object-based neglect. (But see Hillis and Rapp, 1998, for a re-analysis of the data in which they show that some individual subjects exhibit object-based neglect.) Whether this is coincidence or statistically real—and which exact egocentric and allocentric reference frames are implicated—remains to be determined. A further question concerns the relative contribution of each reference frame when neglect is determined by more than one. In those few studies where the data are analyzed such that this question can be addressed, the contribution of each reference frame sometimes appears to be additive and sometimes multiplicative (Behrmann et al., 1998; Behrmann and Tipper, 1998; Calvanio, Petrone, and Levine, 1987). Further investigation of the coupling and relative contributions of different reference frames to spatial coding is clearly required.

The extent to which different reference frames participate depending on the task requirements is also important to understand. As discussed previously, we have shown that it is possible to differentially weight the contribution of a coordinate system depending on the task to be performed (Behrmann and Tipper, 1998). Consistent with this task dependency is the fact that the activity in neurons in posterior parietal cortex differs depending on the task the animal is intending to perform (eye movements versus reaching; Snyder, Batista, and Andersen, 1997).

A final question concerns the neural substrate supporting the computation of the different reference frames. As is clear in the nonhuman primate literature, several distinct regions in the parietal cortex appear to play somewhat different roles (for possible human analogs, see Milner, 1997). Precise localization in a population of neglect patients is extremely difficult, given that the lesion is typically rather large and involves almost all of parietal cortex (and often, additional lobar structures; Vallar and Perani, 1987). A recent neuroimaging study with normal

subjects, however, can shed some light on the issue, suggesting that there might be both common and different regions implicated in location-based and object-based computations. In this study, normal subjects judged the position of a probe on the left or right of an environment frame or of an object frame. Relative to the baseline condition (line length judgment), attending both to an object in left or right space or to the left or right of an individual object revealed an increase in regional cerebral blood flow in left and right superior parietal regions as well as in left inferior parietal regions (as well as some other cortical regions). Additional region activation seen only for the object-based task included left striate and prestriate regions, whereas additional activation associated only with the space-based task included right prefrontal regions and right inferior temporal-occipital cortex (Fink et al., 1997). These findings suggest an overlap in neural mechanisms for different spatial reference representations, but also some divergence between them (see also Egly, Driver, and Rafal, 1994).

The variety of deficits observed following parietal damage suggests that this region of cortex plays a critical role in spatial representation. The parietal cortex, however, does not have a monopoly on spatial processing; regions such as frontal cortex and parahippocampal regions also contribute importantly to spatial representations (see Maguire, 1997; Rainer, Asaad, and Miller, 1998; Robertson and Rafal, chapter 44 in this volume, for more details). How these different areas work together to give rise to our unitary visual experience remains unclear, but neuropsychological studies with patients suffering from hemispatial neglect allow us to observe some of the representations and processes that ultimately contribute to our unified spatial experience.

ACKNOWLEDGMENTS The author thanks Carol Colby, David Plaut, and Mike Posner for useful comments on this manuscript. This work was supported by a FIRST award from the National Institutes of Mental Health (R01 MH5424-6) and by a NIMH Program project grant (MH47566-06).

46 Cortical Mechanisms of Visuospatial Attention in the Primate Brain

LEONARDO CHELAZZI AND MAURIZIO CORBETTA

ABSTRACT Recent functional neuroimaging studies in humans have highlighted a network of cortical regions implicated in the control of visuospatial attention. Critical nodes of this network are regions in the superior frontal and posterior parietal cortices. Single-unit recording experiments in the behaving macaque, together with a number of related functional brain imaging investigations in humans, have further demonstrated that these regions in frontal and parietal cortex house mechanisms for the sensory-controlled guidance of purposeful actions, including motor intention and spatial working memory signals. We propose that these motor intention and spatial working memory signals may correspond to the control signals for the allocation of spatial attention to visual field positions. In addition to modulating sensory processing within the dorsal visual system, control signals for attention have also been shown to bias processing in ventral extrastriate visual areas implicated in the analysis of object features by favoring the processing of objects at attended locations.

Almost without exception, the behavior of humans is governed by an orderly sequence of goals. Some of these correspond to the satisfaction of primary needs, such as providing food and liquids, while others correspond to a virtually endless list of more sophisticated activities and motives born in our modern society, such as picking a book from a bookshelf or locating the correct exit along the highway. Our moment-to-moment cognitive activity is organized around these goals. In this chapter we do not deal with what determines the succession of goals in daily life and its neural correlates. We simply take for granted that goals dominate our mental processes and overt behavior, and that several factors are involved in giving priority to one goal or another at any specific time. Rather, we discuss how implementing a certain goal leads to the selective processing of incoming sensory information—the realm of selective attention. Selective attention is defined as the cognitive function that allows the focusing of processing resources onto the

sensory inputs that are relevant in a given context, and the accompanying withdrawal of resources from inputs that are irrelevant or potentially interfering. In the main, we limit our discussion to recent advancements in understanding the neural mechanisms of *visuospatial* selective attention—advancements that have been obtained by the recording of single neurons from the brain of sub-human primates and by the functional imaging of the human brain with positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

Any visual scene contains multiple objects, where each object is composed of multiple features such as color, shape, motion, and location. Although we can select objects of interest based on any feature or combination of features, the selection of visual objects by location is a powerful way of selecting behaviorally relevant visual information for object recognition. Locations are also selected in the context of a large class of visuomotor behaviors, including orienting to peripheral stimuli by eye (e.g., saccadic), arm (e.g., pointing), or hand (e.g., grasping) movements. Finally, the role of visual locations is emphasized by several theories of higher vision. For instance, Ullman has proposed that the computation of various spatial relations between objects requires the application of visual routines or processes to one or two selected stimulus locations at any given time (Ullman, 1984). The analysis of the whole visual scene therefore requires a mechanism for switching the focus of processing from one location to another. Similarly, Treisman's feature integration theory (Treisman and Gelade, 1980; Treisman, 1991) proposes that the perception of objects in cluttered visual scenes is critically dependent upon an attentional mechanism that selects an object location and binds the features at that location into a unified object percept. Selection of spatial locations, therefore, appears to have broad implications for both perception and action.

One class of paradigms (a class that has enjoyed constant success over the last twenty years) used in exploring visual spatial attention is based on controlled manipulations of stimulus expectancy at specific visual field locations. In these paradigms, observers are induced to focus

LEONARDO CHELAZZI Dipartimento di Scienze Neurologiche e della Visione, University of Verona, Verona, Italy

MAURIZIO CORBETTA Department of Neurology, Radiology, Anatomy and Neurobiology, and the McDonnell Center for Studies of Higher Brain Functions, Washington University, St. Louis, Mo.

their attention on stimuli presented at one location in the visual field and to ignore stimuli presented at other locations while maintaining their gaze on a central fixation target. The direction of the subject's attention can be controlled in two ways: either by means of symbolic cues, usually presented at the center of gaze, in which case we speak of endogenous orienting of attention (e.g., Posner, 1980); or by means of peripheral cues that summon attention automatically to the cued location, i.e., exogenous orienting (e.g., Jonides and Yantis, 1988). Finally, in some studies, instead of using a trial-by-trial cueing procedure, subjects are asked to maintain their attention aligned with a particular spatial location throughout a block of trials, i.e., sustained attention (Van Voorhis and Hillyard, 1977; Tassinari et al., 1987).

Performance is typically enhanced at the attended location, and impaired at the ignored location(s), relative to when attention is uncommitted or evenly distributed across the visual field in advance of stimulus presentation (Posner, 1980). These changes in performance have been shown not only for the simple detection of supra-threshold light stimuli, but also for the detection of near-threshold stimuli and for different types of stimulus identification (e.g., Bashinski and Bacharach, 1984; Downing, 1988). The latter observation is particularly relevant, for it shows that spatial attention has access to functional modules responsible for the specialized processing of visual features and for object perception.

When trying to understand the brain mechanisms underlying spatially selective attention, it is helpful to distinguish the control, or source, signals responsible for directing attention toward a given location from the modulatory effects exerted by these signals on the processing of incoming visual stimuli (attentional modulation of sensory activity). These two sets of signals have different time courses—by definition, control signals must precede the modulation of sensory-driven activity—and, possibly, different distribution within the brain. For example, while the modulation of sensory-driven activity occurs in visual areas implicated in the analysis of the various stimulus features, source signals may additionally involve non-strictly visual areas, which encode and maintain these signals even in the absence of any stimulus in the scene.

In recent years, neuroimaging studies in humans have shown that a network of cortical regions in frontal and parietal cortex is active when attention is directed to visual spatial locations. Similar regions are also recruited during the preparation/execution of eye movements, and possibly other goal-directed motor responses, and when spatial locations are actively remembered for brief periods of time (spatial working memory). Physiological recordings from single neurons in awake behaving pri-

mates have demonstrated that neurons in homologous regions show a combination of sensory, attentional, premotor, and memory signals, presumably participating in the sensorimotor transformations necessary for the control of purposeful actions. Thus, source signals implicated in the allocation of attention to a spatial location may be closely related to the intention to move toward that location (motor preparation signals) and/or to the process of actively remembering that location (working memory signals).

The allocation of attention to a spatial location also causes modulatory changes in extrastriate visual areas involved in the analysis of object features. The net effect of these changes is the amplification of neural signals representing stimuli at attended locations relative to neural signals representing stimuli at unattended locations. This relative advantage can result either from enhanced responses to stimuli at the attended location or from suppression of responses to stimuli at unattended locations, or both. We propose that the frontoparietal cortical network, in addition to participating in the sensorimotor transformations necessary for the guidance of overt behaviors, delivers the control signals that modulate activity in the ventral stream of cortical visual processing.

In the next two sections, we mainly use functional imaging data to highlight the location of frontal and parietal areas that are involved in the control of spatial attention, and single-unit data to discuss the nature of attentional signals in these areas. In the subsequent section, the effects of attention on extrastriate visual areas involved in object processing are considered.

Localization of control systems for spatially selective attention

The role of frontal and parietal cortices in the control of spatial attention had long been recognized on the basis of observations with brain-damaged individuals showing attention-related deficits (hemineglect and extinction) and the analysis of the behavioral disturbances following localized brain lesions in nonhuman primates. For instance, Mesulam (1981, 1990) conceptualized spatial orienting as a complex behavior composed of perceptual, exploratory, and motivational components, with each of these components localized to different cortical regions. In particular, posterior parietal cortex was thought to be involved in the spatial (perceptual) encoding of stimuli, frontal cortex in planning exploratory eye and hand movements toward those stimuli, and cingulate cortex in providing the motivational tone necessary for purposeful orienting. Posner and his colleagues (Posner et al., 1984; Posner and Petersen, 1990) suggested that the allo-

cation of attention to locations/objects involves multiple computational stages, and that these stages may be mapped onto different cortical and subcortical regions. Specifically, directing attention from one object to the next involves disengaging attention from the current object of interest, moving attention onto the new object of interest, and engaging it there. Disengage, move, and engage operations of attention were respectively localized to posterior parietal cortex, superior colliculus, and pulvinar nucleus of the thalamus.

These ideas about visuospatial attention have been more recently tested by recording hemodynamic signals from the living human brain with PET during the performance of cognitive tasks in which subjects covertly directed their attention to peripheral visual stimuli in order to perform visual detection or discrimination. Different studies have manipulated spatial attention in various ways. In some studies subjects were cued to direct attention to different peripheral visual locations to detect the onset of a visual stimulus (Corbetta et al., 1993) or to discriminate its identity (Nobre et al., 1997). In others, subjects voluntarily sustained attention at a single peripheral location to discriminate target stimuli presented in a temporal sequence of distractors (Heinze et al., 1994; Woldorff et al., 1997) or to detect certain target features (e.g., a change in stimulus orientation; Vandenberghe et al., 1996, 1997). Finally, some studies varied the degree of attentional commitment to peripheral stimuli (Corbetta et al., 1995; Vandenberghe et al., 1997). In most experiments sensory activity engendered by the visual stimulation and the motor activity related to the preparation/execution of a behavioral response were appropriately controlled to ensure that the obtained activations reflected either control signals to direct attention to a location or their modulatory effect on incoming sensory information.

Figure 46.1 summarizes these studies by projecting foci of activation localized during different peripheral attention tasks, as compared with an appropriate control condition, on a normalized brain atlas (both 3D view and corresponding surface reconstruction), developed at Washington University by Drury and Van Essen (Drury et al., 1996; Van Essen and Drury, 1997) (see also color plate 30). The control condition in each study was either visual fixation or passive presentation of the same stimuli as in the peripheral attention task. Despite differences in the details of each experiment, and anatomical differences between groups of subjects, a common network of frontal and parietal cortical regions seem to be recruited when people direct attention to peripheral stimuli without moving their eyes. Regions of activation include the postcentral and intraparietal sulcus in parietal cortex, and the precentral sul-

cus/gyrus and the posterior tip of the superior frontal sulcus in frontal cortex. Other regions that have been less consistently activated across studies are the cingulate gyrus, the medial frontal gyrus, and the superior temporal gyrus/sulcus. More recently, a more precise anatomical localization of these functional regions in relationship to specific sulcal or gyral landmarks has been obtained by recording task-related hemodynamic changes with fMRI in single subjects and by projecting the functional data on surface representations of their own brain (see, for example, figure 46.4).

It should be noted that these regions represent areas that are commonly active across experiments. Moreover, in each experiment specific visual and motor areas are active as a function of task demands. Interestingly, tasks that require the simple detection of peripheral stimuli seem to involve predominantly areas of the dorsal visual system. In contrast, tasks requiring the discrimination of objects at peripheral locations involve regions within both the dorsal and ventral stream of processing; and the frontoparietal network is active along with multiple occipitotemporal regions specialized in object processing (Heinze et al., 1994; Corbetta et al., 1995; Vandenberghe et al., 1996, 1997; Woldorff et al., 1997). The only exception to this rule is one study (Heinze et al., 1994), in which subjects discriminated peripheral shapes positioned in the upper visual field. In this study only activations in occipitotemporal cortex contralateral to the direction of attention were reported, without accompanying activations in posterior parietal cortex. Woldorff and colleagues (1997) repeated the same experiment by positioning the stimuli in the lower visual field, however, and obtained robust dorsal, frontoparietal activations. The reason for this discrepancy remains unclear. One interpretation of these general findings is that the frontoparietal network is important for the allocation of attention to peripheral objects, and for their localization, independent of the type of object identification task. Furthermore, selective hemodynamic modulations have been recorded in areas of the ventral visual system, contralaterally to the direction of attention, during object discrimination tasks performed at peripheral locations (Heinze et al., 1994; Vandenberghe et al., 1996, 1997; Woldorff et al., 1997). Correspondingly, the allocation of attention facilitates object discrimination at attended locations (Hawkins, Shafto, and Richardson, 1988; Downing, 1988). The dorsal frontal and parietal regions may therefore be the source of selective spatial biasing signals that enhance visual processing in areas of the ventral visual system specialized for object analysis. Later in this chapter we consider the neuronal correlates of these spatially selective modulatory effects in the ventral visual system.

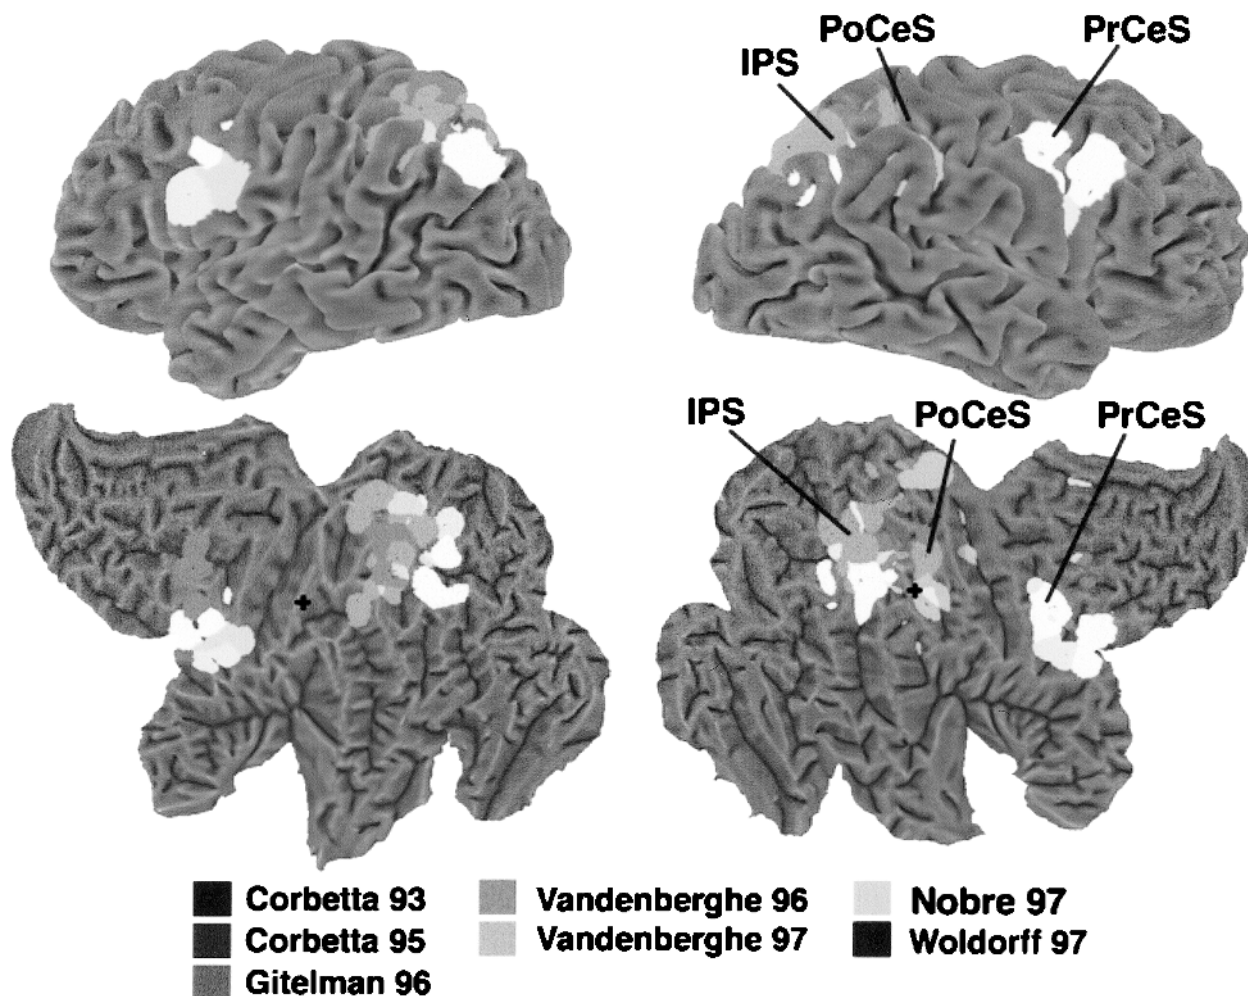

FIGURE 46.1 Frontoparietal cortical network during peripheral visual attention. Common regions of activation across studies include the intraparietal (IPS), postcentral, and precentral sulcus (PrCeS). Foci of activity in each study were mapped onto 3D brain and 2D surface reconstruction of Visible Man

Overall, these studies support the idea that a common network of parietal and frontal areas is recruited when the focus of attention is directed to peripheral visual objects/locations, independent of eye movements. Similar regions seem to be recruited when attention is dynamically moved to different locations or maintained for a prolonged time at the same location (shifting vs. sustained attention). Similarly, the same areas are engaged when attention is voluntarily directed toward a visual object and when it is reflexively drawn to its salient visual features (endogenous vs. exogenous attention). While it is possible that some degree of anatomo-functional segregation will eventually emerge within this cortical network by comparing different modes of spatial attention recruitment in the same subject, the strong anatomical overlap across studies suggests that these regions may play a general role in the allocation of attention to spatial locations.

brain atlas (Drury et al., 1996). The foci are spatially smoothed with a 10-mm radius filter to account for methodological differences across laboratories in entering the standard atlas space (Talairach and Tournoux, 1988; Van Essen and Drury, 1997).

Although the evidence reviewed so far is quite compelling in linking the control systems for spatially selective attention to neuronal activity within a frontoparietal network, these same cortical regions can have other roles in nonspatial forms of attention. This is suggested by some recent functional imaging studies. In one study (Le, Pardo, and Hu, 1998), for instance, subjects were presented with a single stimulus (a colored shape) at the center of gaze, and in separate blocks they were required to perform one of three different tasks: (1) sustained attention to the color of the stimulus, while ignoring its shape; (2) sustained attention to the shape of the stimulus, while ignoring its color; (3) continuous shifts of attention to the color and to the shape of the stimulus in alternating trials. The critical comparison was between the sustained (color or shape) and the shift condition. Regional blood oxygen-

ation in the cerebellum and posterior parietal cortex was measured with fMRI. Attention shifting between visual features produced significant activation bilaterally in superior parietal lobule (extending into the intraparietal sulcus), cuneus, and precuneus, as well as in right lateral cerebellum. Thus, parietal regions may control switches between visual representations even without changes in spatial location. An analogous conclusion has been reached in another study (Lumer, Friston, and Rees, 1998) exploring the neural correlates of perceptual rivalry. In binocular rivalry, dissimilar images are presented to the two eyes and perception alternates spontaneously between each monocular view. Functional brain imaging with fMRI was used to assess the mechanisms underlying the transition between the two alternating perceptual states. Activations specific to shifts in perceptual experience were found in the right inferior and superior parietal lobules and in the right inferior frontal cortex. The right superior parietal activation overlaps with a region active for peripheral attention. Although it is unclear why mechanisms for shifting between visual representations underlying perceptual rivalry should map at least in part onto the same network of areas implicated in visuospatial attention, it is interesting that both cognitive phenomena entail suppression of visual information from conscious perception—information presented at unattended locations in spatial attention tasks, and information relative to either monocular view in binocular rivalry. These frontoparietal cortical networks may therefore play a more general role in regulating the access of competing visual representations to perceptual awareness.

Neuronal signals in frontoparietal cortical networks for spatially selective attention

Data from electrophysiological experiments in the awake monkey can help clarify the neuronal signals in brain networks for spatial attention revealed by functional imaging studies in humans. Single-unit recordings in monkey have shown that spatially directed attention has widespread effects on the responses of neurons in a large number of cortical regions, both in the occipitoparietal and occipitotemporal streams of visual processing, and in functional regions of the frontal lobe. We consider first studies that have investigated how the allocation of attention modifies the neuronal response to visual stimuli during detection or localization tasks (attentional modulation of sensory response); later, we consider neuronal signals that may underlie the allocation and dynamics of attention across the visual field (source or control signals).

ATTENTIONAL MODULATIONS OF SENSORY RESPONSE DURING SPATIALLY SELECTIVE ATTENTION TASKS

Cells in different subdivisions of the posterior parietal cortex of the macaque give enhanced responses to a receptive field (RF) stimulus when the animal voluntarily attends to the stimulus to detect its dimming, compared to when the animal's attention is directed to the foveal target (figure 46.2, top) (Robinson, Goldberg, and Stanton, 1978; Bushnell, Goldberg, and Robinson, 1981; Colby, Duhamel, and Goldberg, 1996). These experiments are usually carried out by instructing the animal to maintain attention at one location for prolonged periods of time. The same enhancement is obtained when the RF stimulus is the target for an immediate or delayed saccade (e.g., Colby, Duhamel, and Goldberg, 1996). These effects have been observed within tissue of the lateral bank of the intraparietal sulcus, area LIP, and nearby gyrus of the inferior parietal lobule, area 7a. A similar enhancement of visual responses has also been observed within a subdivision of the pulvinar nucleus of the thalamus, Pdm, which is interconnected with posterior parietal cortex and has been proposed to play a critical role in selective attention (Petersen, Robinson, and Keys, 1985; Robinson and Petersen, 1992). Enhanced visual responses in area LIP and 7a, and in the pulvinar, have been interpreted as correlates of control signals to direct attention to relevant stimulus locations (Wurtz, Goldberg, and Robinson, 1982; Colby, Duhamel, and Goldberg, 1996). However, these effects are unlikely to reflect the voluntary (or endogenous) allocation of attention to a peripheral location, since attention is presumably deployed at the target location prior to stimulus onset. Other neural signals must necessarily mediate the cognitive process of directing the focus of attention to the location of the stimulus before its appearance. More likely, these modulations reflect the neural correlate of a processing facilitation for sensory stimuli that are behaviorally relevant in a given context.

Interestingly, response modulations of this type have been observed in other cortical and subcortical structures, like the superior colliculus (Goldberg and Wurtz, 1972) and the frontal eye field (FEF; Goldberg and Bushnell, 1981; Wurtz and Mohler, 1976), that are connected to parietal cortex and are more closely involved in the preparation and execution of saccadic eye movements. In other words, the neural facilitation for the processing of target stimuli seems to propagate downstream toward areas involved in response selection and initiation. The enhancement in the FEF was initially reported only when selection of the RF stimulus was contingent on the execution of a saccadic eye movement toward its location, suggesting that it was related specifically to selection of the target for a goal-directed motor response

rather than to spatial attention per se (Goldberg and Bushnell, 1981; Wurtz and Mohler, 1976). This notion, however, might have to be modified. In a series of experiments, Schall and his associates have recently investigated the role of FEF neurons in selecting a target

presented in an array of distractors (Schall and Hanes, 1993; Schall et al., 1995a; Thompson et al., 1996). It was shown that visuomotor neurons in FEF of the macaque signal whether the stimulus in their RF is a target or a distractor, and that this effect is present even

FIGURE 46.2 Response properties in monkey area LIP. Top: Enhancement of the visual response in a single cell when the stimulus becomes behaviorally significant. On the left, the monkey simply fixates a central point while an irrelevant peripheral stimulus appears in the receptive field. On the right, the monkey still fixates the central point but must now attend to the peripheral stimulus to detect a slight dimming. The same stimulus is presented in both tasks, but the response is doubled when the stimulus is made task-relevant. Each panel shows a raster and histogram synchronized on stimulus onset. In the raster display, vertical tic marks indicate the time when an action potential occurred, and each horizontal line shows activity during a single trial. Successive correctly performed trials are aligned on the vertical trigger line. The histogram calibration bar at far left signifies a firing rate of 100 spikes/s. Time lines show horizontal and vertical eye position for a single trial and the time of onset, dimming, and offset for the receptive field stimulus. Bottom: Visual, memory, and presaccadic signals in a single LIP neuron. In the delayed saccade task, the monkey fixates a central point and a visual stimulus is presented in the receptive field for 400 ms (left). After a variable delay, the fixation point is extinguished and the monkey makes a saccade to the location where the stimulus had appeared (right). The same set of trials is aligned on stimulus appearance (left) and on saccade onset (right). Separate visual and motor bursts are seen in each trial, as well as tonic activity during the memory period. (Adapted from Goldberg, Colby, and Duhamel, 1990, and Colby and Duhamel, 1996.)

when eye movements to the target are not allowed (Thompson et al., 1997). Similarly, Kodaka, Mikami, and Kubota (1997) recently provided evidence that the visual response of FEF neurons is enhanced when a stimulus presented at an attended location is detected through a manual response. Frontal regions therefore may be involved as well as posterior parietal cortex in the attentive processing of visual targets during detection or localization tasks.

In the same parietal areas that show a visual enhancement effect during sustained peripheral attention, suppressive effects related to target detection have also been documented during visual orienting tasks in which attention is cued to different locations on each trial. Robinson, Bowman, and Kertzman (1995) have shown that responses of neurons in areas LIP and 7a to a RF stimulus are reduced when the stimulus follows a visual cue presented at the same or at a nearby location. Although peripheral cueing did sometimes result in enhanced responses to the forthcoming target, the more common effect was a response reduction. A similar decrease of responses to expected stimuli, compared to unexpected stimuli, has been observed by Steinmetz and his colleagues (Steinmetz et al., 1994; Steinmetz and Constantinidis, 1995) recording from area 7a during a spatial version of a delayed match-to-sample task. Neuronal responses to matching stimuli (at the cued location) were

considerably reduced compared to responses to nonmatching stimuli (at uncued locations), even when several nonmatching stimuli had intervened.

One interpretation of the above results is that the increased responses to unexpected stimuli in the visual field may be part of a mechanism responsible for redirecting attention in space, i.e., disengaging focal attention from its current focus. This type of attentional signal could provide a way to redirect attention to new, salient locations in the visual field, but cannot be the neuronal correlate of an endogenous voluntary signal that allows the organism to direct attention to any arbitrary location in the visual field irrespective of its sensory saliency.

It is important to note that, among other possible variables, one factor that could explain the prevalence of suppression in the latter studies compared to the enhanced effects in other studies (Robinson, Goldberg, and Stanton, 1978; Bushnell, Goldberg, and Robinson, 1981; Colby, Duhamel, and Goldberg, 1996) could be the use of peripheral, local cues. It is well known from psychophysical experiments in humans that peripheral cues, in addition to engendering facilitatory effects due to the automatic capture of attention toward the cued location, also produce robust inhibitory effects that tend to favor unstimulated locations in the visual field (a phenomenon known as “inhibition of return”; see, for example, Posner and Cohen, 1984; Maylor and Hockey, 1985; Tassinari et al., 1987; Rafal et al., 1989; Tassinari et al., 1994; Rafal, Egly, and Rhodes, 1994; Tipper et al., 1994; Abrams and Dobkin, 1994; Reuter-Lorenz, Jha, and Rosenquist, 1996).

PUTATIVE CONTROL SIGNALS FOR SPATIALLY SELECTIVE ATTENTION Two general ideas have been put forward to explain how the brain directs attention to locations and/or objects. In virtually all tasks, the deliberate allocation of attention to a position in the visual field may require some form of active memory of the location to be attended (spatial working memory). Correspondingly, control signals for selective attention in space may functionally overlap with spatial working memory signals (Desimone and Duncan, 1995; Desimone, 1996). In addition, the tight linkage in natural vision between attention and eye movements (and action systems in general) suggests that the covert allocation of attention to a location may be closely related to the intention to move toward the same location (Rizzolatti et al., 1987; Rizzolatti and Craighero, 1998). In other words, neuronal signals for movements of attention may coincide with preparatory motor signals. These two sets of explanations are not mutually exclusive, as either mechanism may be critical under certain behavioral conditions.

Neurons in frontal and parietal cortex have long been shown to display a pattern of activity that is well suited to store a mental representation (working memory) of a location in space in order to bridge a temporal gap in the task sequence. Tasks used in a number of studies to demonstrate this capability of neurons require the monkey to maintain the location of a briefly presented peripheral stimulus in memory during a blank delay interval, and then to produce a motor response (e.g., a saccade) to the remembered location of the stimulus upon presentation of a go signal (e.g., the offset of the fixation point). In parietal cortex location-specific activity in the retention interval of oculomotor and/or skeleto-motor tasks has been demonstrated both in area LIP and 7a (Andersen, Essick, and Siegel, 1987; Barash et al., 1991; Colby, Duhamel, and Goldberg, 1996; Constantinidis and Steinmetz, 1996), while in the frontal lobe a similar activity has been shown in premotor cortex (di Pellegrino and Wise, 1991, 1993), in dorsolateral prefrontal cortex (Niki and Watanabe, 1976; Funahashi, Bruce, and Goldman-Rakic, 1989; Quintana and Fuster, 1992; Funahashi, Chafee, and Goldman-Rakic, 1993; Rao, Rainer, and Miller, 1997), and in the FEF (Bruce and Goldberg, 1985). Interestingly, while sustained activity specifying a location seems to be abolished by intervening stimuli in area 7a (Constantinidis and Steinmetz, 1996), the same activity survives the interference exerted by intervening stimuli in dorsolateral prefrontal cortex (di Pellegrino and Wise, 1993). Regions in frontal and posterior parietal cortex implicated in spatial working memory are likely to be part (together with other cortical and subcortical structures; Selemon and Goldman-Rakic, 1988) of a distributed network contributing to this function, consistent with the rich reciprocal connections between prefrontal and posterior parietal tissue (e.g., Petrides and Pandya, 1984; Barbas, 1988; Cavada and Goldman-Rakic, 1989; Schall et al., 1995b).

A functional link between spatial working memory and control signals for the allocation of attention has been recently supported by recordings in parietal area LIP. Colby and her colleagues (Colby, Duhamel, and Goldberg, 1996) have shown that neurons in LIP display elevated background firing rates both when the animal has to remember the location of a target presented in the RF of the recorded neuron within the context of a delayed saccade task, and when the animal can anticipate the onset of a relevant visual stimulus inside the RF in a peripheral attention task. This is strong evidence that forming and storing a mental representation of a relevant location in space is a critical component not only in traditional spatial working memory tasks, but also in tasks requiring the deliberate allocation of attention to a specific region of the visual field.

Additional evidence supporting a functional relationship between spatial working memory signals and spatial attentional control signals comes from functional neuroimaging studies in humans. In particular, a number of PET and fMRI studies in humans have revealed activations in posterior parietal and lateral frontal regions (particularly in the right hemisphere) under task conditions requiring the storage and manipulation of spatial information in working memory (see Ungerleider, 1995; Smith and Jonides, 1997, for reviews). In parietal cortex, these activations were typically centered around the intraparietal sulcus and extended into the superior and inferior parietal lobules. In the frontal lobe, activations were usually localized near the precentral sulcus, superior frontal sulcus, and more anteriorly in lateral prefrontal cortex. Figure 46.3 compares regions of activation during studies of peripheral attention (as in figure 46.1) and selected studies of spatial working memory (Jonides et al., 1993; Courtney et al., 1996, 1997, 1998; Owen et al., 1996; Smith et al., 1995; Smith, Jonides, and Koeppe, 1996) (see also color plate 31). All working memory studies involved conditions in which spatial locations were actively remembered and control conditions for sensorimotor factors. The resulting foci of activation were derived by comparing memory conditions against the control condition. The listed studies have been selected because they report the foci of activation in a standard anatomical space that can be used for comparison across conditions and experiments (Talairach and Tournoux 1988). There appears to be strong overlap in posterior parietal cortex, weaker overlap in the precentral region, and preferential activation of the prefrontal cortex during spatial working memory tasks. Interestingly, prefrontal cortex is active in some peripheral attention tasks that require sustained attention (e.g., Vandenberghe et al., 1997), but not in tasks that involve rapid shifts of attention (Corbetta et al., 1993, 1995; Nobre et al., 1997). It is therefore possible that frontal mechanisms of spatial working memory are preferentially involved when locations are maintained on-line for a substantial amount of time, but less so during rapid shifts of attention that occur during spatial cueing tasks. In addition, the recruitment of anterior prefrontal cortex in typical spatial working memory tasks might be due to a greater demand on central executive functions (manipulation of spatial information) in most of these tasks compared to spatial attention tasks.

An important and related issue is whether areas in frontal and parietal cortex that generate and maintain selective spatial signals for the allocation of attention are better conceptualized as "abstract" spatial maps or as nodes of specific sensorimotor systems necessary to perform stimulus guided actions. One possible schema

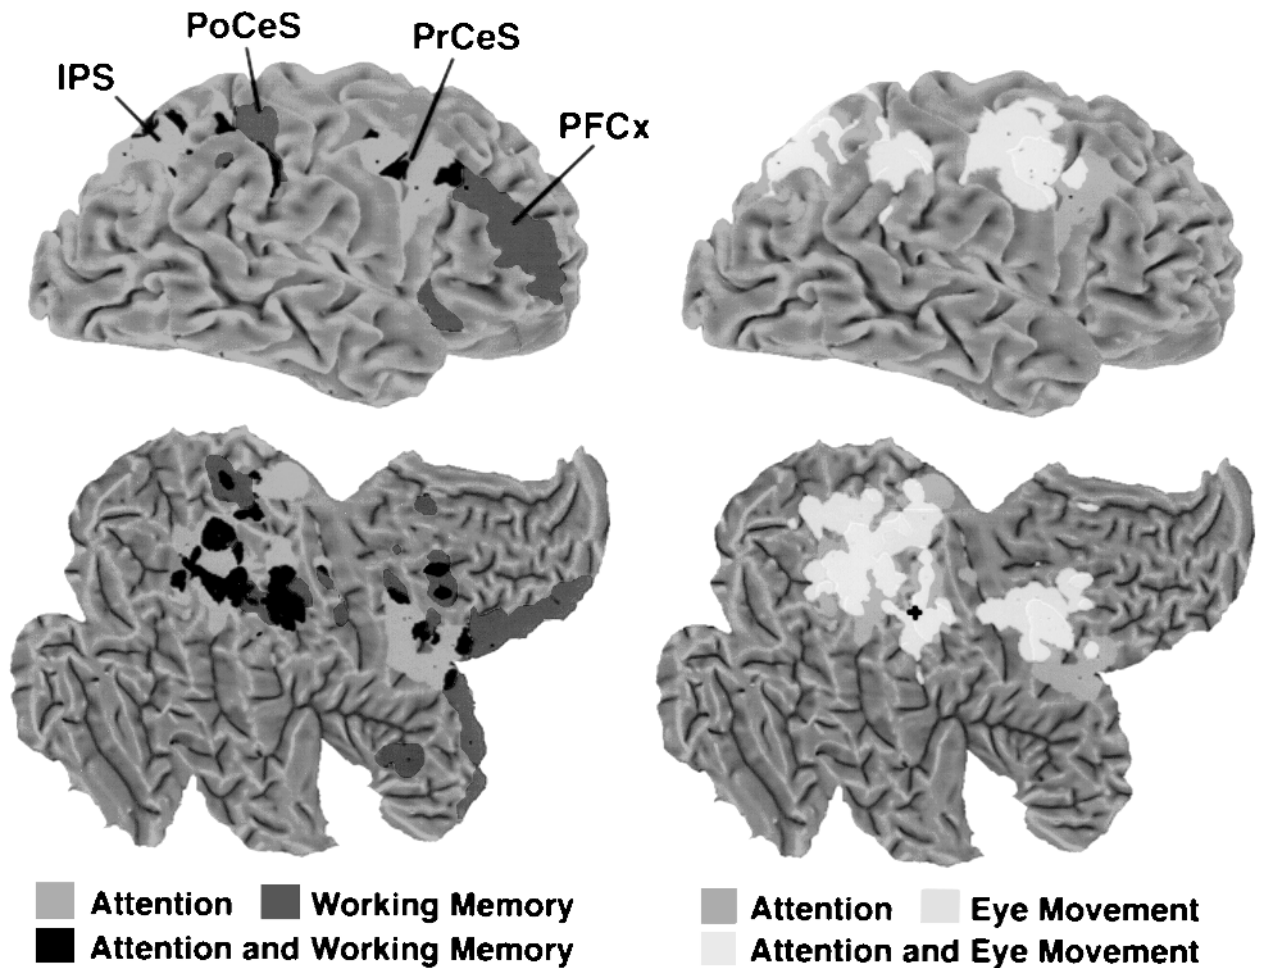

FIGURE 46.3 Peripheral attention vs. spatial working memory vs. saccadic eye movement across studies. 3D and surface reconstruction of right hemisphere of the Visible Man brain atlas. Left: Regions active for peripheral attention (red), regions active for spatial working memory (blue), and regions of overlap (magenta). Studies of attention are the same as those in figure 46.1; for studies of spatial working memory, see text. Note the remarkable overlap in parietal cortex, partial overlap in

precentral region, and exclusive activation of prefrontal cortex (PFCx) for spatial working memory. Other anatomical abbreviations are as in figure 46.1. Right: Comparison between peripheral attention (red) and saccadic eye movements (green) (see text for list of studies). Note the strong overlap (yellow) in both parietal and precentral region. There is no activation in prefrontal cortex.

of the former idea could be that parietal cortex may contain a map of extrapersonal space in which potential locations of interest are “highlighted” by working memory signals from prefrontal cortex. The spatial output of this representation is abstract in the sense that it is not intimately related to any specific action system. This output can be critical across a variety of perceptual tasks, e.g., to gate sensory responses in the ventral visual system during object recognition (Desimone and Duncan, 1995) and/or to conjoin the elemental features of an object (Treisman, 1996). Likewise, it could be critical to initiate a variety of visuomotor responses, e.g., saccadic or reaching movements to a target location. Alternatively, these spatial representations may be intrinsic to specific visuomotor mechanisms for sen-

sory guided responses (e.g., looking, reaching, grasping, navigation).

A view originally proposed by Rizzolatti and colleagues envisioned that neuronal signals necessary to allocate attention to a visual field location correspond to the intention to move the eyes toward the same location, i.e., to preparatory motor activity in spatial oculomotor maps (Rizzolatti et al., 1987; Sheliga, Riggio, and Rizzolatti, 1994, 1995). More recent developments of this theory have generalized this idea to visuomotor systems involved in other sensory guided responses (Rizzolatti and Craighero, 1998; see below). Under this account, the sustained activity recorded during the delay saccade and peripheral attention tasks in parietal area LIP by Colby and colleagues (Colby, Duhamel, and Goldberg,

1996) would be better described as “sustained intentional activity,” reflecting the preparation of an impending eye movement to that location, even when no eye movement is actually performed (Snyder, Batista, and Andersen, 1997).

There is substantial evidence supporting the general view of a tight functional relationship between mechanisms for spatial attention and oculomotor control. First, let us consider the functional properties of neurons in area LIP in posterior parietal cortex and the FEF (area 8) in prefrontal cortex of the macaque, which have long been implicated in the control of saccadic eye movements. Neurons recorded in these two areas display similar properties (Chafee and Goldman-Rakic, 1998), consistent with the dense reciprocal connections (e.g., Petrides and Pandya, 1984), and they have been classified into three distinct classes (Bruce and Goldberg, 1985; Chafee and Goldman-Rakic, 1998)—visual, visuomovement, and movement neurons. Visual neurons have the predominant role of registering a visual event. Visuomovement neurons likely play an intermediate role in transforming a sensory event into a premotor command. Movement cells are more directly implicated in delivering command signals to subcortical structures responsible for activating the eye muscles. We have discussed how neurons in LIP and FEF are capable of encoding the behavioral relevance or saliency of a visual stimulus (see also Gottlieb, Kusunoki, and Goldberg, 1998). In addition, neurons in LIP and the FEF are able to retain location information in working memory for the guidance of delayed oculomotor responses. Thus, these regions seem to be well equipped to perform all the necessary operations to guide purposeful oculomotor responses: the selective encoding of a potential target; the maintenance of target location in memory, if required; and the delivery of command signals to trigger subcortical structures directly responsible for the control of the eye muscles (see figure 46.2, bottom). One could imagine that for neurons in areas LIP and FEF there is actually little formal difference, if any, between coding the relevance of a location of interest in the visual field and coding the intention to make a saccade toward that location.

Second, recent physiological experiments have demonstrated that control signals for location selection may indeed be oculomotor in nature. Kustov and Robinson (1996) have demonstrated that the vector of saccadic eye movements induced by microelectrical stimulation of the deep layers of the superior colliculus is deviated by the presentation of endogenous cues (e.g., a cue at fixation) directing the monkey’s attention toward a visual field location during a manual detection task. Since the monkey was rewarded for maintaining accurate fixation,

these findings would suggest that cognitively induced shifts of attention to a visual location manifest themselves as preparatory saccadic activity in the superior colliculus.

Third, psychophysical experiments in humans have established a tight functional relationship between attentional and oculomotor processes. During natural vision objects of interest are immediately foveated; i.e., shifts of attention in space are accompanied or immediately followed by gaze shifts. While some initial attempts provided somewhat ambiguous results (e.g., Klein, 1980), more recent experiments have shown that voluntary shifts of gaze are typically accompanied by shifts of attention toward the same location (Shepherd, Findlay, and Hockey, 1986; Hoffman and Subramaniam, 1995; Kowler et al., 1995; Deubel and Schneider, 1996) or in the same direction (Chelazzi et al., 1995). So, while it has long been known that attention can be moved across the visual field without concomitant eye movements, eye movements toward a selected visual target seem to involve necessarily the orienting of attention toward the target location.

Fourth, functional neuroimaging studies in humans have demonstrated strong functional overlap between regions of activation in parietal and frontal cortex during peripheral attention and saccadic eye movements. Figure 46.3 compares foci of activation for peripheral attention and saccadic eye movements across selected studies in the literature (Paus et al., 1993, 1995; Anderson et al., 1994; O’Driscoll et al., 1995; O’Sullivan et al., 1995; Petit et al., 1996, 1997; Sweeney et al., 1996; Luna et al., 1998) (see also color plate 31). These studies have explored the brain systems involved in visually guided, memory-guided, and conditionally guided (e.g., prelearned, cue-instructed) saccadic eye movements. Note that the overlap in parietal cortex is comparable to the one obtained with spatial working memory, whereas greater overlap is present in the precentral region. The precentral region contains the human homologue of FEF (Paus, 1996; Courtney et al., 1998). More anterior prefrontal regions (not shown) are active during memory-guided or conditional saccades (e.g., Sweeney et al., 1996; Petit et al., 1996). Corbetta and colleagues have recently compared in the same group of subjects regions of activations for attention and eye movements (Corbetta et al., 1998). Subjects were scanned either during a task in which attention was endogenously shifted to several sequential locations in order to detect visual probe stimuli, while fixation was centrally maintained, or during a task in which eye movement (and attention) shifts were performed toward the same locations. Figure 46.4 shows the functional anatomy of the two tasks in one subject after projection of the activity data on the surface

FIGURE 46.4 Shifts of spatial attention vs. oculomotor/attentional shifts in a single subject. fMRI activity projected on 3D and surface representation of the subject's own brain. Note precise localization of functional activity in relationship to sulcal and gyral landmarks. TOS = transverse occipital sulcus; IPS = intraparietal sulcus; STS = superior temporal sulcus;

CeS = central sulcus; PrCeS = precentral sulcus; MeFG = medial frontal gyrus; CiS = cingulate sulcus; FO = frontal operculum. Note that the degree of overlap between attention and saccadic eye movement regions is much higher than in group data (cf. figure 46.3, right).

reconstruction of his own brain (see color plate 32). All regions active for eye movements, including the putative homologue of FEF (precentral sulcus region), supplementary eye field (SEF; medial frontal gyrus), and LIP/7a (intraparietal sulcus) were also active during the covert attention task. No region was uniquely active in one or the other condition, and the degree of overlap in each region across subjects was between 60 and 80%.

In summary, these data support a view by which control (source) attentional signals for directing the focus of processing toward a given visual field location may coincide with preparatory oculomotor signals to make a saccade toward the same location. However, one should be cautious in emphasizing this link between eye movements and spatial attention. It may turn out that, although the functional link between these two processes perhaps enjoys a privileged status, a similar functional relationship and sharing of neuronal machinery exists between spatial attention and any other system for the programming and execution of sensory controlled motor responses, such as reaching, grasping, and navigation. For instance, selective attention to an object for the purpose of reaching toward its location might correspond to premotor signals in areas involved in the control of reaching responses rather

than eye movements. Several findings suggest this possibility.

In the macaque, the pattern of anatomical connectivity and the physiological properties of the neurons have led to a subdivision of the posterior parietal cortex into a number of areas (e.g., Andersen et al. 1990, 1997; Colby, Duhamel, and Goldberg, 1993; Colby, and Duhamel, 1996; Colby, 1998). Each of these areas is specialized both in terms of its dominant sensory input (e.g., visual vs. somatosensory), or combination of inputs, and its competence with respect to motor output (e.g., eye movements vs. reaching vs. grasping). In addition, each area has been shown to code spatial locations in a frame of reference that is most appropriate for the specific type of motor response being controlled (e.g., Colby, 1998). Likewise, a number of areas specialized with respect to different motor behaviors have been identified in premotor and prefrontal cortex (Kurata, 1994; Preuss, Stepniewska, and Kaas, 1996; Wise et al., 1997; Graziano and Gross, 1998). Functional modules in posterior parietal and frontal cortex, together with interconnected cortical and subcortical structures, work in concert to perform the relevant sensorimotor transformations required to control a specific motor behavior. One example of this functional frontoparietal interplay

is represented by the LIP-FEF circuit that we considered previously. Other circuits have been described for the control of different types of movement, such as the one comprising area VIP in the intraparietal sulcus and area F4 (or ventral premotor) in the frontal lobe for the control of arm and head (mouth) reaching (e.g., Colby, Duhamel, and Goldberg, 1993; Fogassi et al., 1996; Gentilucci et al., 1988; Graziano, Hu, and Gross, 1997; Graziano and Gross, 1998) and the one comprising area AIP in the rostral intraparietal sulcus and frontal area F5 (rostral ventral premotor) for the control of grasping (e.g., Rizzolatti et al., 1988; Taira et al., 1990; Sakata and Taira, 1994; Jeannerod et al., 1995; Murata et al., 1996).

As noted previously, one prediction of the hypothesis that spatially selective attention is closely related to premotor signals in general, and not uniquely to oculomotor signals, is that control signals for attention should be carried by the activity of neurons implicated in reaching whenever a specific object in the field is selected in order to produce a reaching response toward its location. An indication that the relevance of a visual target is not uniquely coded by the activity of neurons in cortical networks for eye movements comes from recent experiments by Snyder and colleagues (Snyder, Batista, and Andersen, 1997, 1998). In these experiments, the monkey was required to produce either a saccade or a reach response toward a designated stimulus location. It was found that activity of intraparietal neurons specifically related to one or the other type of motor behavior was determined by the response being planned and executed (saccade vs. reach). Changing the motor plan toward a selected stimulus location from an eye vs. arm movement, without a change in the direction of attention, determined which neurons were more active prior to movement onset. This result indicates that the activity of these cells reflects the animal's intention to make a particular motor act, rather than a general attentional signal. If the activity were simply related to attention, then the activity should be indifferent to the type of movement actually performed (see Platt and Glimcher, 1997, for a related finding). More generally, this suggests that control signals reflecting the allocation of attention to visual field locations are not an exclusive prerogative of neurons involved in oculomotor behavior.

In accord with the idea that control signals for spatial attention are intrinsic to cortical networks other than those implicated in eye movements, lesion studies in monkeys have demonstrated contralesional attention deficit following damage to cortical regions implicated in other types of motor behaviors. For example, Rizzolatti, Matelli, and Pavesi (1983) showed that monkeys with lesions of area 6 in premotor cortex, an area known to be involved in reaching with the arm and the mouth,

had severe contralesional neglect for peripersonal but not far extrapersonal space.

Finally, there is some recent evidence in humans that the preparation of a manual reaching response, in the absence of eye movements, causes enhanced sensory processing of stimuli at the location selected for the movement. Deubel and Schneider (1998) required subjects to prepare and execute a reaching movement toward a cued target location, and also to discriminate alphanumeric characters presented at varying distances from the cued location just prior to, or simultaneously with, the onset of the movement (dual-task paradigm). They found that the discrimination of alphanumeric stimuli was optimal when their location coincided with the target location of the arm movement. One interpretation of this result is that the preparation of an arm movement toward a given visual field location yields enhanced perceptual processing at that location, similarly to what happens with saccadic eye movements.

The reviewed evidence is in line with several recent and less recent proposals emphasizing a fundamental functional link between mechanisms for the preparation and execution of overt motor actions and mechanisms for the orienting of covert attention in space (Neumann, 1987; Allport, 1987; Tassinari et al., 1987; Rizzolatti et al., 1987; Rizzolatti and Craighero, 1998).

Effects of spatial attention on object recognition mechanisms in the ventral visual system

We have noted that the frontoparietal cortical network may be the source of spatially selective modulations in the ventral visual system during object discrimination tasks performed at peripheral locations. In particular, many studies have demonstrated that the hemodynamic response to peripheral visual stimuli is enhanced when attention is directed toward them as compared to when attention is directed away from them, e.g., to the opposite visual field (see Heinze et al., 1994; Woldorff et al., 1997; Vandenberghe et al., 1996; Mangun et al., chapter 48 in this volume; Wojciulik, Kanwisher, and Driver 1998; Clark et al., 1997). The regions of activation in ventral extrastriate visual cortex include cortex near the collateral sulcus, fusiform, and parahippocampal gyri, which have been shown to be specialized for object feature analysis (shape, color, faces; e.g., Corbetta et al., 1991; Haxby et al., 1994). These hemodynamic modulations are spatially coincident with ERPs effects on the same tasks (Heinze et al., 1994; Woldorff et al., 1997). Hereinafter, candidate correlates of these effects at the single-cell level are considered.

Moran and Desimone (1985) were among the first to document the profound influence of spatial attention on

the activity of cells in area V4 and the inferotemporal cortex. In their study, stimuli were simultaneously presented at two locations in the visual field and the monkey was instructed to perform a delayed match-to-sample task on the stimuli at one location while ignoring stimuli at the other location. One of the stimuli in a pair was selected to be an effective sensory stimulus for the cell when presented alone, whereas the other stimulus was selected to be an ineffective stimulus. In one condition both stimulus locations were confined to the RF of the recorded neuron, while in another condition one stimulus location was inside and the other was well outside of the RF under study. With both stimulus locations inside the RF, the critical comparison was between trials where the monkey attended to the location containing the effective stimulus and trials where the monkey attended to the location containing the ineffective stimulus. In both area V4 and IT cortex responses to the effective stimulus inside the RF were profoundly suppressed when attention was directed to the ineffective sensory stimulus. Suppressed responses to the effective sensory stimulus inside the RF were not observed in V4 when attention was directed to an ineffective stimulus outside the RF boundary (this was never the case in IT cortex due to the large RFs in this area).

This pattern of results has been confirmed by Luck and colleagues (1997) in a recent investigation of the effects of spatial attention on visual responses in areas V1, V2, and V4. As in the study of Moran and Desimone (1985), Luck's group had their monkeys attend to stimuli at one location in the visual field and ignore stimuli simultaneously presented at another location, in order to detect a deviant stimulus in a rapid temporal sequence of nontargets (figure 46.5A). Neurons in area V2 and V4 showed suppressed responses to an effective sensory stimulus presented inside their RF when the animal attended to an ineffective stimulus located within the same RF boundary (figure 46.5B). Suppression of responses to the effective stimulus inside the RF was almost absent in the same two areas when attention was directed to a location outside the RF border (figure 46.5C).

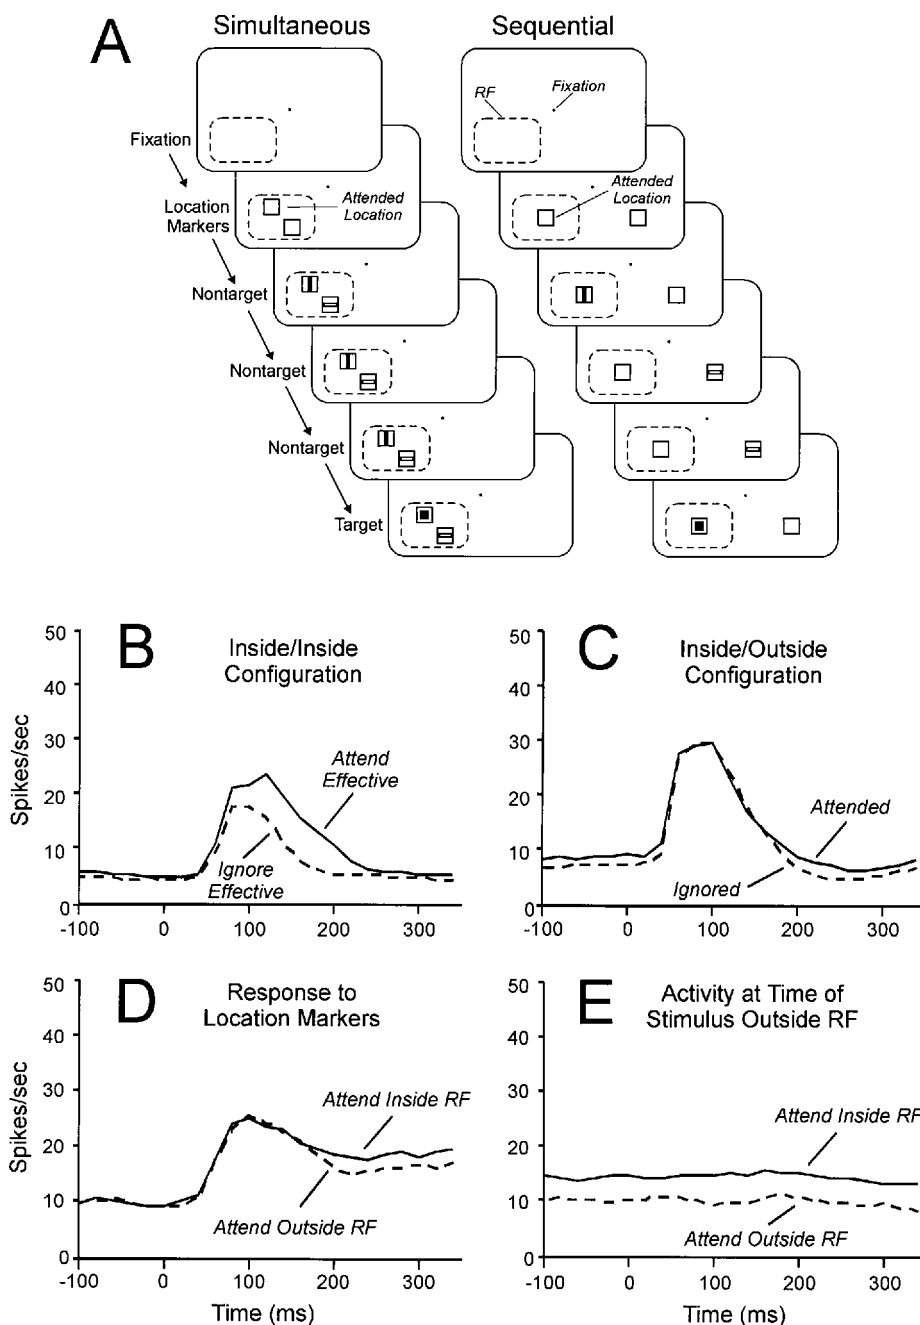

Overall, these findings suggest that spatial attention gates neuronal responses in the ventral visual system by suppressing activity related to irrelevant stimuli when they are located near relevant stimuli, but not when they are located far away from them. An intriguing implication of these findings is that competition between stimuli positioned far apart in opposite visual fields cannot be resolved at the level of the visual system, since even in inferotemporal cortex (the area with the largest RFs in the visual system) RFs do not cover the entire visual field. It should be noted, however, that other studies have reported substantial effects of directed spatial at-

tention on the response of neurons in areas V2 and V4 even in the absence of multiple competing stimuli inside the RF of the individual neuron (Motter, 1993; Connor et al., 1997). It is conceivable that under certain conditions effects of attention can be observed with a single stimulus inside the RF; nevertheless, it is also plausible that greater and more consistent effects are typically obtained by placing multiple stimuli within one RF boundary (see Treue and Maunsell, 1996, for a similar finding in the motion-sensitive areas MT and MST).

Of course, another question arises: Why have a number of single-unit recording experiments shown this predominant effect of attention within a restricted region of space when no similar spatial constraint is typical in psychophysical, ERPs, or brain imaging investigations in humans documenting robust effects of directed attention for stimuli located across opposite visual fields? There might be many potential explanations for this discrepancy, but one possibility is that the extracellular recording of the spiking activity of single neurons in visual cortex does not capture some critical neural codes reflecting the allocation of attention to spatial locations. For example, standard single-unit recordings would not detect systematic temporal correlations in the firing of neuronal populations within an area, while these might underlie important behavioral, surface electrical, or hemodynamic modulations related to attention.

A different type of neuronal modulation has been reported in ventral extrastriate visual cortex, whose characteristics match those of a spatially selective control signal (source signal). Luck and colleagues (1997) reported that the baseline activity of neurons in areas V2 and V4 was elevated when the animals were directing their attention to a location inside the RF, relative to when attention was directed outside the RF. Importantly, the baseline shift was greater when attention was aligned with the most sensitive portion of the RF and diminished progressively as attention was moved toward the RF border. This indicates that the spatial signal responsible for this effect has a spatial resolution higher than the size of a typical RF in these areas. This elevation of baseline firing was evident from the beginning of the trial (figure 46.5D)—i.e., prior to the onset of any task-relevant stimulus in the visual field—and persisted in all the intervals between stimulus presentations (figure 46.5E).

The sustained increase of baseline activity in areas V2 and V4 has the hallmarks of a control attentional signal by virtue of its spatial selectivity and independence from sensory input. It is also suggestively similar to the sustained activity recorded in LIP (Colby, Duhamel, and Goldberg, 1996) both during a spatial working memory task and a peripheral attention task. We have previously proposed that a frontoparietal cortical network in

humans, likely including regions homologous to LIP, is the source of spatially selective effects in the ventral visual system. A relatively straightforward prediction of this proposal is that sustained baseline effects in V2 and V4, as shown by Luck and colleagues (1997), should be abolished by transient deactivation with muscimol or other agents of regions involved in attentional control, e.g., LIP or FEF.

Some models have been developed to explain how selective (e.g., spatial) biasing signals may influence the neuronal response of neurons to attended and unattended objects. One such model is the biased competi-

tion model, which was inspired by the previous results obtained in areas V2, V4, and the inferotemporal cortex in the context of spatially selective attention tasks and other attention-related effects in these areas (Chelazzi et al., 1993, 1998; Chelazzi and Desimone, 1994; Desimone and Duncan, 1995; Luck et al., 1997). According to this model, objects in the visual field activate corresponding neural populations distributed across several cortical (and subcortical) visual structures. These neural populations are part of reciprocal inhibitory networks. As a consequence of this widespread architecture, object representations engage in competitive interactions.

FIGURE 46.5 Schematic description of the task and results from the study of Luck and colleagues (1997). (A) Example stimulus sequences in representative trial types. The two sets of displays illustrate simultaneous (left) and sequential (right) stimulus presentation, which were equally used for the recording of cells in the different conditions. In both cases the trial began with the monkey holding a response lever and fixating a target at the center of a computer monitor. Shortly after, location markers were shown, indicating the spatial locations where stimuli would be presented. According to special instruction trials, one location was relevant throughout a block of trials, while the other was irrelevant. The opposite was true in the subsequent block. The task of the animals was to signal with a lever release the onset of a target stimulus (a square) presented at the relevant location in a sequence of nontargets (rectangles), and to ignore stimuli presented at the irrelevant location. The spatial arrangement of the stimuli was varied systematically. In some cases (left) both stimulus locations were positioned within the RF of the recorded cell; in other cases (right) one stimulus location was positioned inside the RF while the other location was outside. In the former case, one stimulus inside the RF was selected to be effective at driving the cell's response when presented alone, while the second stimulus was selected to be ineffective. Note that the "inside/inside" and "inside/outside" stimulus configurations are depicted here for the simultaneous and sequential trials, respectively, although the opposite pairing of spatial configuration and temporal sequence was used as well. (B) Poststimulus histograms averaged over 29 V4 cells for effective and ineffective stimuli presented simultaneously inside the RF (left in A). The two curves compare responses to the RF stimuli when the location of the effective (solid line) or of the ineffective (dashed line) stimulus was attended. Activity was much higher when attention was directed to the effective stimulus in the pair. Using this inside/inside configuration, similar results were obtained with sequential stimulus presentation. (C) Poststimulus histograms averaged over 38 V4 cells showing response to RF stimulus during sequential presentation (right in A) as a function of attention. The solid line represents attention directed to the stimulus location inside the RF, and the dashed line represents attention directed to the stimulus location outside the RF. In this condition attention had no consistent effect on the population average sensory-driven response. A similar lack of modulation was obtained in the inside/outside configuration with simultaneous stimulus presentation. (D) Activity at the beginning of the trial for 40 V4 cells recorded with the inside/outside configuration and sequential stimulus presentation. Shortly after the onset of the location markers, i.e., before any task relevant stimulus was presented, baseline activity was higher when the animal's attention was directed to the stimulus location inside the RF compared to when attention was directed to the location outside the RF. (E) Activity of the same cells shown in D during the time periods in which a nontarget stimulus was presented outside the RF, indicating that the baseline shift persisted throughout the course of the trial.

These interactions are typically stronger when objects in the field activate nearby neural populations—for instance, when objects in the field are close to one another. Competitive interactions are influenced both by

bottom-up, or stimulus-driven, factors, such as the relative contrast of the stimuli in the field (Reynolds, Pasternak, and Desimone, 1996), and by top-down feedback factors, such as the greater behavioral relevance of one stimulus over another, specified in working memory (Chelazzi et al., 1993, 1998; Luck et al., 1997). Two aspects of the results by Moran and Desimone (1985) and by Luck and colleagues (1997) are particularly consistent with the biased competition model. On the one hand, the model can explain why effects of directed attention are heavily constrained by spatial factors—i.e., the suppression of responses to an effective stimulus inside the RF of a neuron is mainly observed when attention is directed to a nearby location inside the same RF. This is due to the fact that competitive interactions are particularly strong among neurons whose RFs cover the same region of space. In turn, the reason for this is that the need for attentional mechanisms is related to the need to resolve the ambiguity when multiple stimuli impinge on a single RF, i.e., when they compete for the encoding capacity of a single neuron. On the other hand, the shift in baseline activity prior to stimulus onset in both areas V2 and V4 when the animal's attention is directed to the RF is consistent with the idea of a spatial signal that biases the competition in favor of the neural representation of stimuli at the attended location.

Conclusions

The ability to direct attention to extrapersonal locations in visual space is a critical biological function of higher organisms. Functional neuroimaging studies in humans and physiological recordings in awake behaving primates are beginning to elucidate the anatomical and physiological organization of brain systems mediating this function. In particular, a network of cortical regions that include the posterior parietal cortex and the frontal eye field is involved in generating neural signals that allow processing resources to be focused on one object of interest in the visual scene—although some evidence suggests the same frontoparietal network may play a more general role in the coordination of visual representations and visual awareness. Control signals for the allocation of attention in space may correspond to spatially selective premotor or working memory signals. Spatially selective source signals from the frontoparietal network bias neuronal activity in extrastriate visual areas involved in object analysis, and this is reflected in changes of baseline firing prior to stimulus onset and modulation of the sensory-evoked responses. The net effect of these changes is the amplification of neural signals representing stimuli at attended locations and the attenuation of neural signals representing stimuli at unattended locations. Future work

will have to uncover through which routes control signals for spatially selective attention flow from frontoparietal to occipitotemporal extrastriate cortical areas, and through which cellular mechanisms they can affect processing of visual stimuli in the latter areas. However, the greatest conceptual and empirical challenge for the years to come will perhaps be to clarify the boundaries, or to delete them, between spatial attention, spatial working memory, and motor intention signals in the primate brain.

ACKNOWLEDGMENTS Preparation of this chapter was supported by NEI grant EY00379, The Charles A. Dana Foundation, and the McDonnell Center for Higher Brain Studies (MC) and by Human Frontier Science Program Organization (HFSPO) grant RG0136/97 and grants from Italian MURST and CNR (LC). We would like to thank Dr. Steve Petersen for suggestions and discussion on an early draft of the manuscript. We also thank Dr. Carol Colby for kindly providing figure 46.2, and Mr. Marco Veronese for helping preparing figure 46.5.

47 The Operation of Selective Attention at Multiple Stages of Processing: Evidence from Human and Monkey Electrophysiology

STEVEN J. LUCK AND STEVEN A. HILLYARD

ABSTRACT Because of its finite computational resources, the human brain must process information selectively in a variety of domains. For example, we may limit processing to a subset of the many possible objects that could be perceived, a subset of the many possible memories that could be accessed, or a subset of the many possible actions that could be performed. Although the fundamental need for selective processing is present at each of these stages, there are important differences in the computations performed by different cognitive systems; hence it is likely that substantially different attentional mechanisms are responsible for selective processing at each stage. It has been difficult, however, to isolate the attentional mechanisms that operate in different cognitive systems, primarily because behavioral outputs typically reflect the combined effects of several stages of processing. In this chapter, we describe the application of electrophysiological techniques to the isolation of attentional operations at different stages of processing, including perception, working memory, and response selection.

During almost every waking moment, the human brain is confronted with a vast amount of information—thoughts, memories, and emotions—and innumerable sensory inputs from every modality. To avoid being overwhelmed by this cacophony, the brain relies on mechanisms of selective attention that limit processing to a subset of the available information. The resulting selectivity is easily observed in everyday human behavior: We generally focus our thoughts and conversations on a small number of topics at any given moment, and we typically notice and remember only a fraction of the objects and events we encounter. Moreover, because we have but two hands, two feet, and one mouth, our ac-

tions are typically directed toward a small number of tasks at any one time.

Although the effects of selective attention on behavior are ubiquitous, the internal mechanisms by which information is selected are just beginning to be understood. Indeed, the pervasiveness of selectivity is partly responsible for the difficulty of understanding how attention operates, because a given behavioral sign of selective attention could potentially reflect internal selectivity within any of the various cognitive subsystems that underlie a given behavior. Over the past 25 years, the techniques of cognitive neuroscience have played an increasingly important role in helping to analyze the level of processing at which information is selected and to understand the neural substrates of the selection process.

In this chapter, we focus on two fundamental and interrelated issues in the study of attention. The first issue is the classic “locus-of-selection” question, which asks whether attention operates at an early, perceptual stage or at a late, postperceptual stage. Previously, we have stressed the operation of attention at early stages (Hillyard et al., 1995), but here we discuss conditions under which attention operates at intermediate and late stages as well as at early stages. The second issue to be addressed in this chapter is the question of exactly why selective attention is needed at certain stages of processing. For many years, psychologists were satisfied with the proposal that cognitive processes were simply limited in capacity and that attention was used to allocate some sort of processing resource. But it is now possible to specify more exactly how selective attention may solve specific computational problems that arise in cognitive processing, such as the so-called “binding problem,” which occurs when independently coded attributes of an object must be combined (Luck, Girelli, et al., 1997; Treisman, 1996).

STEVEN J. LUCK Department of Psychology, University of Iowa, Iowa City, Iowa

STEVEN A. HILLYARD Department of Neurosciences, University of California, San Diego, La Jolla, Calif.

Several neuroscience techniques can be used to study attention, but in this chapter we focus primarily on event-related potentials (ERPs) in humans and single-unit recordings in monkeys. ERPs are voltage deflections that can be recorded on the scalp at the time of a stimulus, a response, or some other measurable event. These voltage deflections typically arise from summated postsynaptic potentials in the cerebral cortex that are passively conducted through the brain and skull to the scalp, where they can be recorded noninvasively from normal volunteers (reviewed in Hillyard and Picton, 1987). As illustrated in figure 47.1, the ERP waveform following a stimulus consists of several positive (P) and negative (N) deflections called “waves” or “components.” The sequence of components following a stimulus reflects the sequence of neural processes triggered by the stimulus, beginning with early sensory processes and proceeding through decision- and response-related processes. The amplitude and latency of the successive peaks can be used to measure the time course of cognitive processing, and the distribution of voltage over the scalp can be used to estimate the neuroanatomical loci of these processes. ERPs have two main advantages over traditional behavioral measures in the context of attention research. First, they provide a continuous measure of processing between a stimulus and a response, making it possible to determine the stage or stages of processing that are influenced by attention. Second, ERPs provide a means of covertly measuring the processing of a stimulus—without requiring an overt response—which is very useful for assessing the processing of unattended stimuli. However, the spatial resolution of the ERP technique is limited, and so we also discuss data obtained from other human neuroimaging techniques and from recordings of single-unit activity in monkeys.

Multiple stages of selection

Across a wide variety of conditions, it can be shown that people are faster and more accurate at detecting attended stimuli than unattended stimuli. However, the origins of such effects have been debated since the 1950s, with some researchers arguing that attended stimuli are better perceived than unattended stimuli (the “early-selection” position) and others arguing that perceptual processing is unaffected by attention and that selective processing occurs only at postperceptual stages, such as working memory and response selection (the “late-selection” position). It is beyond debate that atten-

tion does sometimes operate at a late stage—after all, there are clearly occasions when an individual fully perceives a stimulus but chooses not to make an overt response to it. The burden of proof therefore rests on the shoulders of those who argue that attention operates at an early stage. As we discuss in the next section, neurophysiological studies have now conclusively demonstrated that attention operates at early stages as well, at least under some conditions. Thus, attention may oper-

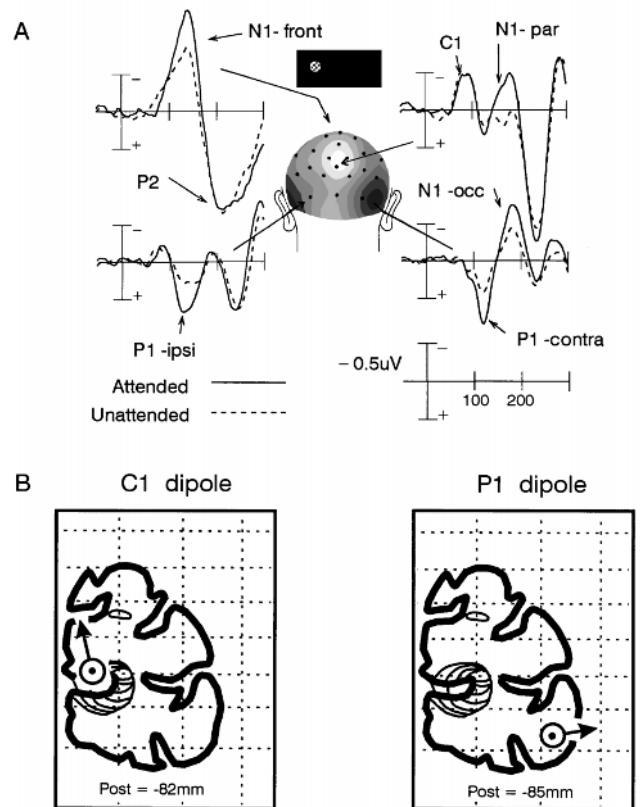

FIGURE 47.1 Stimuli and results from a typical ERP attention experiment (Clark and Hillyard, 1996). In experiments such as this, the subject fixates a central point and attends to either the left or right visual field. Stimuli are flashed to the left and right fields in a rapid, randomized sequence, and the subject responds to occasional targets embedded among frequently occurring nontargets in the attended field. (A) Grand average ERP waveforms from four different scalp sites, showing the C1, P1, and N1 components. The P1 and N1 components were larger for attended-location stimuli than for unattended-location stimuli, but the C1 component was unaffected by attention. The scalp map shows the distribution of voltage from 60–85 ms. In this time period, the C1 wave appears as a negative potential (indicated by light gray) at the midline, and the P1 wave appears as a positive potential (indicated by dark gray) at lateral occipital sites. (B) Estimates of the C1 and P1 dipole sources, projected onto coronal brain sections derived from the atlas of Talairach and Tournoux (1988). These best-fit dipoles were calculated from the scalp voltage distributions using the BESA algorithm (Scherg, 1990). (Reprinted with permission from Hillyard, Teder-Sälejärvi, and Münte, 1998.)

ate at either early or late stages of processing (or both), and the task for attention researchers has now shifted to determining what conditions lead to attentional selection at a given stage of processing.

We propose that a simple principle determines the stage at which attention operates: The presence or absence of attentional selection at a given stage of processing depends on the presence or absence of interference at that stage, which in turn depends on the stimuli and task. For example, consider a task in which red and green letters are presented individually at fixation at a rate of one letter per second, and the subjects are required to remember all the red letters, reporting them at the end of a 15-second trial block. The visual system could easily identify both the red letters and the green letters at this slow stimulus presentation rate; therefore, no selective processing of the red letters would be expected at the stage of perception. However, the limited capacity of working memory would make it difficult for most subjects to retain both the red and the green letters, so only the red letters would be selected for storage in working memory. In contrast, a very different pattern of selectivity would be expected if 14 green letters and 1 red letter were presented simultaneously in a densely packed array and the subject were required to report the identity of the red letter as quickly as possible. In this case, the memory load would be relatively modest, but the green letters might interfere with the perception of the red letter, thus necessitating a perceptual-level filtering of the green letters (i.e., early selection). Perceptual-level interference may also arise with individually presented stimuli under certain conditions, such as when the stimuli are presented at such low intensities that spontaneous neural noise becomes a significant source of interference (Hawkins et al., 1990).

By this account, the locus of selection is directly determined by the stage or stages of processing at which interference is present for a given stimulus-task combination (for a related account, see Lavie, 1995). Although this is a useful conceptualization of the locus-of-selection issue, it is difficult to test unless there is an independent means of determining the conditions under which interference will be present at a given stage. In the following sections, we describe conditions that would be expected to lead to interference at three coarsely defined stages of processing—namely, perception, working memory, and response selection.

Evidence for selection at the perceptual level

THE ONSET TIME OF SELECTIVE PROCESSING The application of the ERP technique to the locus-of-selection issue relies on straightforward logic: If attention operates

at an early stage, then the early sensory-evoked ERP waves should be enhanced for attended stimuli relative to unattended stimuli, whereas if attention operates at a late stage, then only the later ERP waves should be affected. Several studies have used this logic in combination with variants of the experimental paradigm illustrated in figure 47.1A. In this paradigm, subjects fixate a central point while stimuli are flashed at predefined locations in the left visual field (LVF) and the right visual field (RVF). Subjects are instructed to attend to the LVF in some trial blocks and to the RVF in other trial blocks, and they are required to respond when they detect an infrequent target stimulus that occurs occasionally among the nontarget stimuli at the attended location. The stimuli are presented rapidly, making it difficult for the subjects to detect the targets without the use of focused attention. Under these conditions, numerous studies have shown that the initial P1 and N1 waves are larger in amplitude for stimuli presented at the attended location than for stimuli presented at the unattended location (reviewed in Hillyard, Vogel, and Luck, in press).

There are several reasons to believe that the modulation of P1 amplitude by spatial attention reflects a modulation of perceptual rather than postperceptual processing. First, the P1 component is an obligatory sensory response from the occipital cortex (see below) that is sensitive to stimulus factors such as contrast and stimulus position and is insensitive to cognitive factors (with the exception of spatial attention). Attentional modulations of this component are therefore most readily attributable to changes in sensory processing (Johannes et al., 1995; Wijers et al., 1997). Second, this effect typically begins 70–90 ms after stimulus onset, at which time visual information is only beginning to reach the object recognition areas of the inferotemporal cortex. Third, effects of this nature have been observed only in studies of spatial attention and have not been observed when attended and unattended stimuli are presented at the same location and differ in other stimulus dimensions such as color (Hillyard and Anllo-Vento, 1998). If attention operates after stimulus identification is complete, there would be no reason to expect that the dimension of spatial location would be treated any differently from other stimulus dimensions (e.g., see Bundesen, 1990), whereas a special mechanism for selection by location is entirely consistent with the topographically organized representations used in the early and intermediate stages of visual processing. Finally, equivalent P1 attention effects are observed regardless of the task-relevance of a stimulus. In particular, P1 amplitude modulations are observed both for targets and nontargets, and even for task-irrelevant “probe” stimuli that are occasionally flashed at the

attended and unattended locations but do not resemble the task-relevant stimuli (Heinze et al., 1990; Luck, Fan, and Hillyard, 1993). Presumably, any attention effects that operate after a stimulus has been identified would be limited to task-relevant stimuli, because there would be little point in attending to a stimulus already identified as task-irrelevant. In contrast, any attention effects that occur before identification is complete must necessarily be insensitive to the identity of the stimulus. It should also be noted that results of this nature have been observed in the visual search and spatial cuing paradigms, which are frequently used to assess the behavioral effects of selective attention (Luck, Fan, and Hillyard, 1993; Luck and Hillyard, 1995; Luck et al., 1994; Mangun and Hillyard, 1991).

NEURAL SITES OF SELECTIVE ATTENTION Although the P1 attention effect almost certainly represents a modulation of perceptual processing, it is not yet clear exactly which specific substages of perception are being modulated or which specific areas of visual cortex are subject to attentional control. To provide more specific information about the locus of selection within perception, recent studies have attempted to determine the neuroanatomical sources of the ERP attention effects and have recorded single-unit activity in specific areas of visual cortex in monkeys.

Recordings of ERPs from midline parieto-occipital scalp sites typically include a component called *C1* that has an onset latency of 50–60 ms, which is even earlier than that of the P1 (see figure 47.1A). Two sources of evidence indicate that the C1 wave is generated in primary visual cortex (V1). First, as shown in figure 47.1B, dipole modeling procedures have indicated that the C1 scalp distribution is consistent with a generator source in area V1. Second, the scalp distribution and polarity of the C1 wave change as a function of stimulus position in the visual field, and these changes correspond closely to the known retinotopic projections of the upper versus lower visual fields upon the striate cortex within the calcarine fissure (Clark, Fan, and Hillyard, 1995; Mangun, Hillyard, and Luck, 1993). Several studies have found that the C1 wave is unaffected by spatial attention under conditions that lead to significant modulations of P1 amplitude (Clark and Hillyard, 1996; Gomez Gonzales et al., 1994; Mangun, Hillyard, and Luck, 1993), which indicates that the initial sensory response in V1 is not affected by attention [although attention may influence V1 at a later point in processing (see Aine, Supek, and George, 1995)]. In contrast, the neural generators of the P1 wave can be accurately modeled by dipoles in extrastriate cortical areas (figure 47.1B), and the effects of attention on the P1 wave suggest that spatial attention first

influences visual processing in extrastriate areas of visual cortex.

To assess the neural locus of the P1 attention effect more precisely, Heinze and colleagues (1994) conducted a study in which subjects performed a variant of the attention task shown in figure 47.1 during both an ERP recording session and a positron emission tomography (PET) session. The P1 attention effect was found to be associated with an increase in blood flow in the ventral occipital lobe in the posterior fusiform gyrus, and dipole modeling indicated that the scalp distribution of the P1 attention effect was consistent with a generator source in this region. Mangun and colleagues (1997) subsequently reported that both the P1 attention effect and the increase in fusiform blood flow are influenced similarly by task manipulations, thereby reinforcing the hypothesis that the two measures reflect the same underlying neural activity. A second area in the medial occipital gyrus also showed an effect of attention on blood flow. For stimuli presented in the lower visual field, however, Woldorff and colleagues (1997) observed increased blood flow and an associated P1 dipole in a dorsal extrastriate area of the occipital lobe, with a secondary focus in the fusiform gyrus. Although the specific areas affected by attention vary among the experiments, these combined PET and ERP data strongly indicate that early perceptual selection takes place in extrastriate visual cortex.

Converging evidence concerning the localization of attentional modulation was provided by a recent study in which single-unit activity was recorded from macaque monkeys while the animals performed a task similar to that shown in figure 47.1 (Luck, Chelazzi, et al., 1997). As shown in figure 47.2A, many neurons in area V4 exhibited larger responses to attended-location stimuli than to unattended-location stimuli. Figure 47.2B plots the difference in the response to the attended- and unattended-location stimuli, showing that the effect of attention began at 60 ms poststimulus, which is the same time as the beginning of the stimulus-evoked neural response. Thus, attention appears to operate as a preset filter that modulates the initial afferent volley of activity through area V4. In addition, as in the case of the P1 attention effect, this modulation of single-unit activity was identical for target and nontarget stimuli (see figure 47.2C). In contrast, no consistent effects of attention were observed in a parallel set of recordings from area V1, which is consistent with the lack of any attention effect for the C1 wave in ERP recordings. Together, the ERP, PET, and single-unit results provide compelling evidence that selective attention can modulate perceptual processing in extrastriate visual cortex, at least under cer-

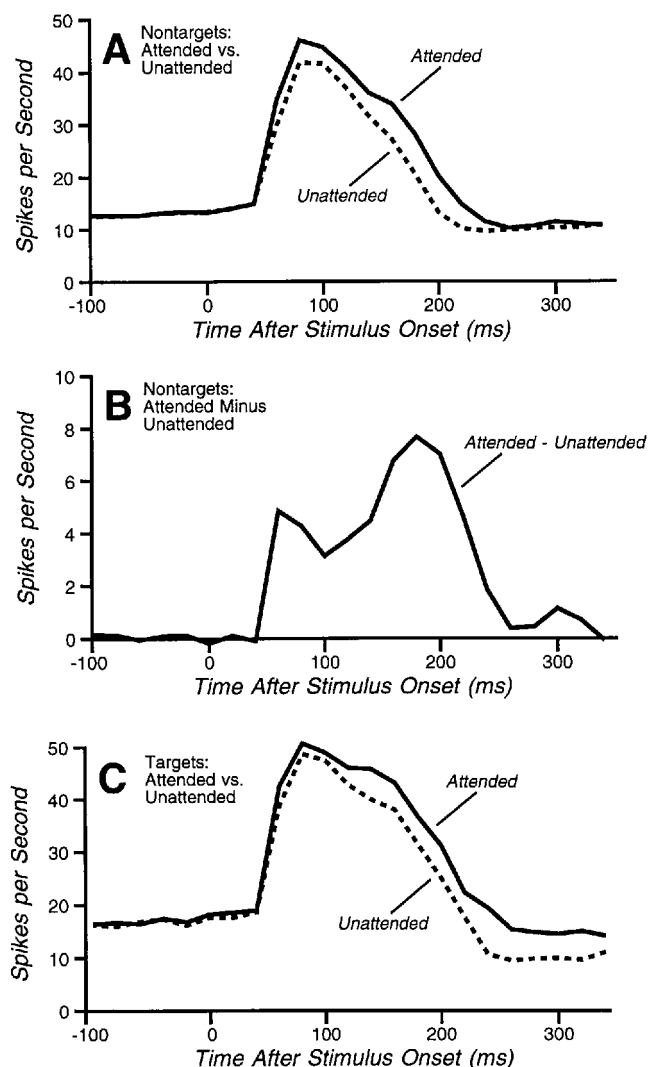

FIGURE 47.2 Single-unit responses recorded from area V4 in the study of Luck and co-workers (1997a). (A) Average post-stimulus histograms from 37 neurons that showed a significant difference in the response to an attended-location stimulus compared to an unattended-location stimulus. These responses were elicited by nontarget stimuli. (B) Difference between the responses to attended- and unattended-location stimuli. Note that this difference deviates from zero at approximately 60 ms, which is the same time as the onset of the sensory response. (C) Responses to target stimuli presented at the attended and unattended locations. (Adapted with permission from Luck, Chelazzi, et al., 1997.)

tain conditions (see also Connor et al., 1996; Moran and Desimone, 1985; Motter, 1993).

Conditions leading to early selection

As discussed above, we propose that attention will operate at a given stage of processing only when there is interference at that stage. Lavie and her colleagues have similarly argued that attention operates at an early stage

only under conditions of high perceptual load (Lavie, 1995; Lavie and Tsal, 1994). Consistent with these proposals, early attentional modulations of neural activity have been observed only when a significant perceptual load was imposed by requiring speeded responses, by using difficult-to-detect targets, by surrounding the target with competing nontarget stimuli, or by presenting the stimuli at a very rapid rate (e.g., see Luck, Fan, and Hillyard, 1993; Luck et al., 1994; Mangun and Hillyard, 1991). As detailed below, these are conditions that are likely to create perceptual-level interference and are thus likely to lead to perceptual-level attention effects. In particular, there are at least two different types of interference arising at the stage of perception that may be alleviated by selective attention. The first of these is interference among multiple objects, which can lead to binding errors (i.e., errors caused by incorrectly combining features that belong to different objects), and the second is interference from spontaneous neural activity.

THE BINDING PROBLEM The problem of correctly binding together the features of an object can arise at many stages of the nervous system, and one variant of this problem is illustrated in figure 47.3. This figure shows the responses of a set of four idealized V4 neurons that are selective for different features but have overlapping receptive fields. When a red horizontal bar is presented (figure 47.3A), the red-selective and horizontal-selective neurons are activated and the stimulus is coded correctly. Similarly, when a green vertical bar is presented (figure 47.3B), the green-selective and vertical-selective neurons are activated and the stimulus is again coded correctly. However, when the red horizontal and green vertical bars are presented simultaneously (figure 47.3C), all four neurons are activated and the neural coding becomes ambiguous; in particular, it is not possible to determine from these neurons whether the display contains a red horizontal bar and a green vertical bar or a green horizontal bar and a red vertical bar. In the terms used by Treisman and Schmidt (1982), the presence of multiple stimuli within the receptive fields of these cells may lead to “illusory conjunctions.”

Luck, Girelli, and colleagues (1997) recently proposed an “ambiguity resolution theory” of attention, which postulates that ambiguity in neural coding can be resolved by an attentional mechanism that limits processing to a single object at any given moment. If the inputs from the other objects are momentarily suppressed, then the neurons that remain active must necessarily correspond to the attended object (figure 47.3D). The theory also proposes that such filtering will be necessary only under conditions that lead to ambiguous neural coding. For example, when an observer is required simply to de-

FIGURE 47.3 Illustration of the binding problem in visual cortex. The areas enclosed in broken lines represent the overlapping receptive fields of four neurons in area V4, each of which is selective for a different feature (red, green, horizontal, and vertical). A plus sign indicates that the neuron responds to the stimulus and a minus sign indicates no response. When only a single red horizontal bar is present (A), only the red-selective and horizontal-selective cells fire, and when only a single green vertical is present (B), only the green-selective and vertical-selective cells fire. However, when both bars are present simultaneously (C), all four cells fire and it is impossible to determine which features belong to the same object. This problem can be solved by an attentional mechanism that suppresses the responses to the unattended objects (indicated by the gray shading in D), such that the neural responses reflect only a single object. Importantly, the binding problem is not present when two objects are present but only one falls inside the receptive fields (E). In this case, the neurons unambiguously signal the features of the stimulus inside the receptive field.

tect the presence of red in a stimulus array, there is no ambiguity because the response of the red-selective neurons unambiguously signals the presence or absence of the color red, independently of the other objects in the display [as long as the colors of the objects are easily discriminable (see Treisman and Gormican, 1988)]. In addition, a neuron's responses are ambiguous only when multiple stimuli are presented inside its receptive field; when only a single object falls inside the receptive field, the neuron's response unambiguously codes the features of that object (figure 47.3E).

Evidence supporting this view of attention has been obtained in several single-unit recording studies (Chelazzi et al., 1993; Luck, Chelazzi, et al., 1997; Moran and Desimone, 1985; Treue and Maunsell, 1996), one of which is summarized in figure 47.4. Panel A of this figure shows the responses obtained from an individual neuron in area V4. When the monkey performed a simple fixation task, this neuron gave a large response to a blue vertical bar presented alone and a small response to a green horizontal bar presented alone. When the two stimuli were presented together and the monkey was instructed to attend to one of the two stimulus locations, the response of the cell was modulated by attention such that the response elicited by both stimuli presented simultaneously was similar to the response to the attended stimulus presented alone (figure 47.4B). In other words, when the monkey attended to the blue vertical bar, the response to the pair of bars was large, just like the response to the blue vertical bar presented alone; when the monkey attended to the green horizontal bar, the response to the pair of bars was small, as was the response to the green horizontal bar presented alone. Thus, attention appeared to filter out the contribution of the unattended stimulus.

Figure 47.4C shows the effects of attention averaged over a population of 29 neurons in area V4. Again, these neurons gave a larger response when attention was directed to an effective stimulus (i.e., a stimulus that elicited a large response regardless of attention) than to an ineffective stimulus (i.e., a stimulus that elicited a small response regardless of attention). As shown in figure 47.4D, however, this effect was eliminated when only one of the two stimuli was inside the receptive field and the other stimulus was outside the receptive field.

The effects of attention have been assessed in areas V1, V2, V4, and MT of the occipital lobe and also in inferotemporal cortex (Chelazzi et al., 1993; Luck, Chelazzi, et al., 1997; Moran and Desimone, 1985; Treue and Maunsell, 1996). In all of these areas, the results have suggested that strong attention-related modulations of sensory activity occur primarily when multiple stimuli are presented inside the classical excitatory receptive field (or so close to the receptive field that they

FIGURE 47.4 Single-unit responses recorded from area V4 in the study of Luck and co-workers (1997a). (A) Responses of a single neuron to a blue vertical bar and to a green horizontal bar, presented individually inside the receptive field. (B) Responses of the same neuron when the two stimuli are presented simultaneously inside the receptive field and attention is directed to the blue vertical stimulus in some trial blocks and to the green horizontal stimulus in other blocks. (C) Average response across 29 neurons when attention is directed to an effective or an ineffective stimulus when both are presented simultaneously inside the receptive field. (D) Average response across the same neurons when only one of the two stimuli is located inside the receptive field. (Adapted with permission from Luck, Chelazzi, et al., 1997)

would be expected to indirectly influence the response of the cell). Receptive fields are so small in area V1 that it is virtually impossible for an animal to attend to one stimulus inside the receptive field and ignore another that is also inside the receptive field, and attention effects have only rarely been observed in this area (Motter, 1993). In area V2, receptive fields are only slightly larger, but attention effects have been observed in the subset of V2 cells with large enough receptive fields to contain both an attended and an unattended stimulus (Luck, Chelazzi, et al., 1997). In V4, most receptive fields are large enough to contain multiple stimuli, and two studies have found that the effects of attention are substantially larger when multiple stimuli are presented inside the receptive field (Luck, Chelazzi, et al., 1997; Moran and Desimone, 1985). A similar result has been reported for area MT (Treue and Maunsell, 1996). In inferotemporal cortex, the receptive fields are so large that it is difficult to place a stimulus outside the receptive field, and the majority of cells in this area exhibit large attention effects (Moran and Desimone, 1985). As will be discussed later, attention effects have sometimes been observed in extrastriate cortex in the absence of multiple stimuli inside the receptive field (Connor et al., 1996; Motter, 1993; Spitzer, Desimone, and Moran, 1988; Treue and Maunsell, 1995), but all studies that have compared multiple stimuli inside the receptive field to a single stimulus inside the receptive field have found substantially larger attention effects in the former condition. These results are consistent with the proposal that attention operates to resolve ambiguities in neural coding that arise when multiple stimuli influence the response of a neuron.

Two questions are often asked in the context of these results. First, how is it possible for a neuron to “know” when multiple stimuli are present inside its receptive field? The answer to this question is not yet known, but we assume that the local circuitry within each visual area contains the information necessary to determine—at least coarsely—when a potentially ambiguous stimulus configuration is present. Second, why is attentional filtering limited only to a subset of neurons? The answer to this question is relatively straightforward: There is a cost to throwing away information. For example, it appears that neurons in area V4 achieve color constancy by integrating wavelength information across broad areas of the visual field, and widespread filtering within V4 might impair color constancy. Everyday experience also supports the proposal of limited filtering, because we do not experience the sort of “tunnel vision” that would result if most of the visual scene were filtered at a given moment. Thus, it is reasonable to suppose that attention is used sparingly and

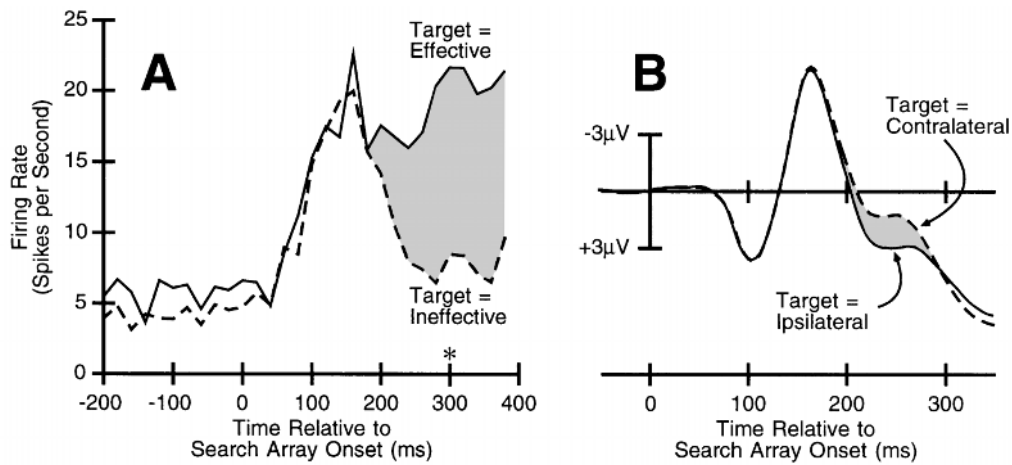

FIGURE 47.5 (A) Single-unit responses recorded from inferotemporal cortex in the study of Chelazzi and colleagues (1993), averaged over 22 neurons. Target and nontarget stimuli were presented simultaneously inside the receptive field, and the monkey was required to make a saccade toward the target (mean saccadic reaction time is indicated by the asterisk). In some trials, the target was an effective stimulus and the nontarget was an ineffective stimulus for the neuron being recorded, and in other trials, this was reversed. The neurons initially gave a large response whether the target was an effective or ineffective stimulus, but beginning around 175 ms poststimulus, the response became suppressed if the target was an ineffective

stimulus. In other words, the cell initially responded to both stimuli, but eventually coded the features of the target exclusively. (B) Analogous ERP results from the study of Luck and colleagues (1997b). In this experiment, a distinctly colored target was embedded in an array of distractor items and the subject was required to press one of two buttons to indicate the target's shape. The ERP response was initially insensitive to the location of the target, but beginning around 175 ms, the response was more negative at electrode sites contralateral to the target compared to sites ipsilateral to the target; this effect is called the N2pc component (for N2-posterior-contralateral). (Adapted with permission from Luck, Girelli, et al., 1997.)

that neural responses are suppressed only when neural coding becomes ambiguous.

The short-latency attention effects shown in figure 47.4 were obtained when attention was precued to a location before stimulus onset, and similar but delayed effects are found when the location of the to-be-attended object is not known in advance. In visual search tasks, for example, it appears that neurons in extrastriate cortex initially provide a coarse preattentive coding of the entire visual field so that a potential target can be located, followed by the focusing of attention onto this item for complete identification. This is illustrated in an experiment reported by Chelazzi and colleagues (1993), in which monkeys were presented with two items simultaneously and were required to determine if either of them was a target item. As shown in figure 47.5A, when one of the stimuli was an effective stimulus and the other was an ineffective stimulus for the neuron being recorded, the neuron initially gave a large response. Beginning around 175 ms poststimulus, however, the neuron's firing became suppressed if the target was the ineffective stimulus but continued unabated if the target was the effective stimulus. In other words, after an initial preattentive period—during which the neuron simply signaled the presence of an effective stimulus—the neuron's output began to reflect only the properties of the target stimulus. As in the case of pre-

cued attention, these effects were larger when both stimuli were inside the receptive field.

An analogous set of results has been obtained in ERP recordings from human subjects (Luck, Girelli, et al., 1997). In particular, modulations of an occipital ERP component called the N2pc wave (shown in figure 47.5B) closely resemble the monkey single-unit suppression effect shown in figure 47.5A. In addition to having a similar onset time, the N2pc wave is affected by a variety of experimental manipulations in the same manner as the single-unit attention effects observed by Chelazzi and his colleagues (Chelazzi and Desimone, 1994; Chelazzi et al., 1993). Specifically, the N2pc component is larger for conjunction discrimination tasks than for feature detection tasks, is larger when a target is surrounded by nearby distractor items, and is larger when a simple feature must be localized than when it must simply be detected. Thus, in both human and nonhuman primates, one major role of attention is to resolve the ambiguous neural coding that occurs when multiple items are presented within a neuron's receptive field.

THE PROBLEM OF INTERNALLY GENERATED NOISE
Despite the wide applicability of the ambiguity resolution theory, attention effects have also been observed under conditions that would not be expected to lead to ambiguous neural coding (Mangun and Hillyard, 1991;

Motter, 1993; Spitzer, Desimone, and Moran, 1988). For example, attended stimuli have sometimes been found to elicit larger responses than unattended stimuli even though these stimuli were presented sequentially and at widely separated locations (Mangun and Hillyard, 1988; Motter, 1993). Such effects have been observed primarily when the stimuli were difficult to identify or when a limited amount of time was available for perceiving or responding to the stimuli. To explain these modulations of sensory responses, several researchers have proposed that attention operates like a sensory gain control, amplifying attended channels compared to unattended channels (Hawkins et al., 1990; Hillyard, Vogel, and Luck, in press; Treisman, 1964). It is important to note, however, that increasing the gain of an input source will not always lead to an improvement in perceptual performance, because both the signal and the noise contained in the input will be amplified. A gain control mechanism can be useful, however, when perceptual performance is limited by the brain's internal noise rather than by noise in the input. As an analogy, imagine listening to a high-fidelity musical recording through headphones in a quiet room. At low volumes, one's own breathing and heartbeat may make it difficult to hear the music clearly, and turning up the volume even slightly may significantly improve the clarity with which the music is heard. In contrast, imagine listening to a very poor recording at a moderate volume level. Owing to the noise in the input source, the music may be very difficult to perceive clearly, but turning up the volume provides no improvement because an increase in gain increases the noise as well as the signal. Thus, an attention-controlled sensory gain control mechanism would be useful whenever performance is limited by internal noise rather than by noise in the input source.

There are many experimental tasks in which a simple gain control mechanism would be useful. For example, when an observer is required to discriminate between two similar colors, any intrinsic variability in spontaneous neural activity may impair discrimination performance, and increasing the gain at an early stage in the system would minimize the effects of the spontaneous activity. Similarly, when an observer is asked to make a very rapid response, a decision must be made before the visual system has acquired much information about the stimulus, and internal noise could lead to erroneous responses. In addition, high rates of stimulus presentation may increase internal noise levels because the neural responses elicited by irrelevant stimuli may contribute noise during the processing of relevant stimuli, and a sensory gain control mechanism may again prove useful under such conditions. These are exactly the conditions under which gain control-like modulations of sensory

responses have been observed (e.g., Mangun and Hillyard, 1988; Mangun and Hillyard, 1991; Spitzer, Desimone, and Moran, 1988). Thus, it appears that attention plays at least two roles at the stage of perceptual processing—namely, resolving ambiguous neural coding by suppressing competing input sources and improving signal-to-noise ratios by controlling sensory gain.

Conditions leading to late selection

SELECTION IN VISUAL WORKING MEMORY The term “working memory” refers to the temporary storage of information that can be manipulated according to task demands. Working memory has been divided into multiple subsystems, with a separate storage module for each sensory modality and a single central executive process that coordinates storage, manipulation, and retrieval for each module (see Baddeley, 1986). In this chapter, we concentrate on visual working memory, but similar principles apply to other types of working memory as well.

Working memory has at least two characteristics that make selective attention essential for its efficient operation. First, it is well known that the storage capacity of working memory is strictly limited, with a prototypical capacity of 7 ± 2 items in the domain of verbal working memory (Miller, 1956). The capacity of visual working memory is also quite small, with a limit of approximately 4 objects (Luck and Vogel, 1997). Consequently, it is important to store only the most relevant objects in working memory to avoid overloading its limited storage capacity. Second, the process of encoding an object into a durable form in working memory appears to be slow and resource-demanding. For example, Potter (1976) showed that subjects could identify pictures of complex, real-world scenes at very rapid rates of presentation (9 pictures per second), but they could not store the pictures in working memory at such rates. This result suggests that visual perception is typically much faster than working memory storage, and a selection process is therefore necessary to control which of the many perceived objects are stored in working memory.

Visual perception suffers from interference when many items are presented simultaneously at different locations, whereas working memory appears to be impaired when items are presented rapidly at a single location. These factors led us to propose that attention will begin to operate at the stage of perception in the former case and at the stage of working memory in the latter (Luck, Vogel, and Shapiro, 1996; Vogel, Luck, and Shapiro, in press). Evidence for this hypothesis has been derived from studies of the *attentional blink* phenomenon. When subjects view rapid sequences of stimuli, the

FIGURE 476 Stimuli and results from the attentional blink study of Raymond and colleagues (1992). Sequences of stimuli were presented rapidly at the fixation point, and at the end of each trial the subject reported the identity of the one letter that had been presented in white and indicated whether an X had been presented.

detection of a target is typically followed by a period of approximately 500 ms during which subsequent targets are missed; this impairment in the detection of subsequent targets is called the attentional blink because it is similar to the impairment that would occur if the first target triggered an eyeblink (Chun and Potter, 1995; Raymond, Shapiro, and Arnell, 1992; Shapiro, Raymond, and Arnell, 1994). As illustrated in figure 47.6A, for example, Raymond and colleagues (1992) presented subjects with rapid sequences of letters at the fixation point and asked the subjects to make two responses on each trial, the first to indicate the identity of the first target (T1, a white letter) and the second to indicate the presence or absence of the second target (T2, the letter X). In addition, a control condition was run in which subjects ignored T1 and reported only the presence or absence of T2. Figure 47.6B shows accuracy for detecting T2 as a function of the lag between T1 and T2. When the subjects were required to report both T1 and T2, T2 accuracy was severely impaired when T2 followed T1 by two to five items. However, when subjects were instructed to ignore T1, T2 accuracy was uniformly high at all lags, which indicates that the mere presence of T1 did not disrupt T2 performance. Thus, the allocation of attention to T1 resulted in a period of time during which T2 could not be reported (i.e., an attentional blink).

Initially, Raymond and colleagues (1992) suggested that the attentional blink reflects errors in the perceptual

processing of T2, but they and others have more recently proposed that the attentional blink reflects an impairment at the later stage of working memory (Chun and Potter, 1995; Shapiro, Raymond, and Arnell, 1994). In other words, the visual system can identify every item in the stimulus stream, but subjects cannot store T2 in working memory while they are busy trying to store T1, and the perceptual representation of T2 is therefore overwritten by the subsequently presented stimuli (see Giesbrecht and Di Lollo, in press). This hypothesis was recently tested in a series of electrophysiological experiments in which T2-elicited ERPs were recorded in the attentional blink paradigm (Luck, Vogel, and Shapiro, 1996; Vogel, Luck, and Shapiro, in press).

The most informative experiment focused on the N400 component, which is highly sensitive to the degree of mismatch between a word and a previously established semantic context (Kutas and Hillyard, 1980). For example, a large N400 would be elicited by the last word in the sentence, “He put the towels in the washing machine and added a cup of POPCORN,” but not by the last word in the sentence, “He put the towels in the washing machine and added a cup of DETERGENT.” Similar results are obtained in experiments using sequentially presented word pairs: A larger N400 is elicited by the second word if it deviates from the semantic context established by the first word [e.g., a larger N400 is elicited by the second word in lime-NICKEL than in lime-LEMON (see Kutas and Hillyard, 1989)]. Because a semantic context violation cannot be detected before the word’s meaning has been assessed, the presence of a larger N400 component for a mismatching word indicates that the word has been identified to the point of lexical/semantic access. Therefore, the presence of a normal N400 component during the attentional blink period would provide strong evidence that words presented during the attentional blink are fully identified, even though the observer cannot accurately report them.

This prediction was tested in an attentional blink experiment in which T2 was a word that either matched or mismatched a semantic context established at the beginning of each trial. The results of this experiment are summarized in figure 47.7. Consistent with previous attentional blink experiments, T2 accuracy was impaired when T2 was the third item following T1 (lag 3) compared to when T2 was the first or seventh item following T1. In contrast, the N400 component was not suppressed during the attentional blink period, which indicates that the words were identified to the point of lexical/semantic access during this period, even though behavioral discrimination accuracy was substantially impaired. To demonstrate that the N400 component is actually sensitive to perceptual

FIGURE 47.7 (A) N400 amplitude and T2 accuracy from the study of Vogel, Luck, and Shapiro (1998). When T2 was the third item after T1, T2 accuracy dropped dramatically, but there was no suppression of the N400 component. (B) Results from an additional experiment in which simultaneous visual noise was added to T2 and subjects were not required to report T1. As more noise was added, accuracy and N400 amplitude both declined, indicating that the N400 component is sensitive to manipulations of perceptual quality. (Data from Vogel, Luck, and Shapiro, in press. Copyright © 1998 by the American Psychological Association. Adapted with permission.)

impairments, an additional experiment was conducted in which varying amounts of visual noise were added to the T2 stimulus, making it more difficult to perceive. This manipulation had a substantial influence on N400 amplitude, demonstrating that the N400 is quite sensitive to changes in perception. These results therefore provide strong evidence that attention operates at a postperceptual stage when stimuli are presented in a rapid sequence at a single location rather than being presented simultaneously at multiple locations.

To determine more precisely the stage at which processing is impaired during the attentional blink, an additional experiment was conducted to examine the P3 wave, which occurs after the N400 component and has been proposed to reflect the updating of working memory (Donchin, 1981). Unlike the N400 component, the P3 wave was found to be completely suppressed during the attentional blink period. This provides additional evidence for a role of attention in limiting the storage of information in working memory.

SELECTION DURING RESPONSE PROCESSING ERP recordings have also been used to examine even later stages of processing, such as the response selection processes that may be subject to attentional control when multiple responses must be made in a short period of time. For several decades, cognitive psychologists have studied this type of dual-task interference by means of the psychological refractory period (PRP) paradigm, which is illustrated in figure 47.8. In a typical PRP experiment, two targets (T1 and T2) are presented on a given trial, and the subjects is required to make a separate speeded response to each target. When the SOA be-

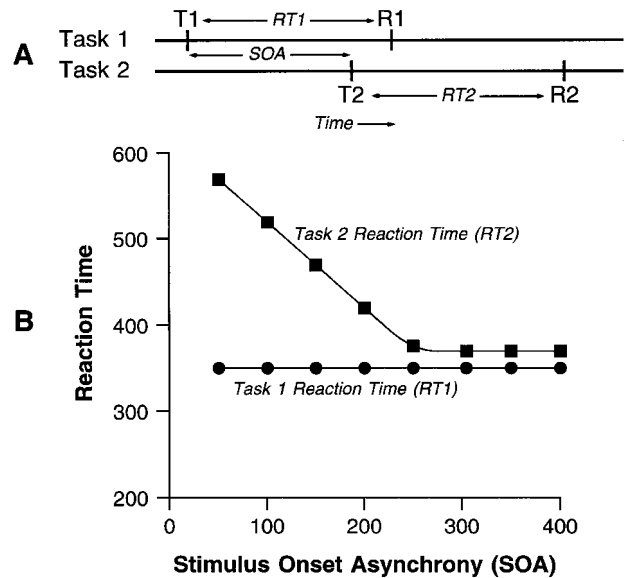

FIGURE 47.8 Paradigm (A) and results (B) from a typical PRP experiment. On each trial, two targets are presented (T1 and T2), separated by a variable SOA. Independent responses are made to the two targets (R1 and R2), resulting in two reaction times on each trial (RT1 and RT2).

tween T1 and T2 is sufficiently long, the processing of T1 has completed before the processing of T2 begins, and no interference is observed. When the SOA is shortened, however, the processing of T1 interferes with the processing of T2, and the T2 response is delayed (McCann and Johnston, 1992; Welford, 1952). On the basis of behavioral experiments, Pashler (1994) has argued that this slowing of RTs is caused by interference at the stage of response selection, with minimal interference in perceptual or motor processes.

This proposal is consistent with the general model of attention presented here. Perceptual interference between T1 and T2 is not a plausible explanation for the slowed responses, because the basic PRP phenomenon is very robust even when the targets are very simple and are presented in different modalities. Similarly, interference in working memory is not a likely explanation because this task does not overload the storage capacity of working memory and because there are no masks that might overwrite the perceptual representations of the targets before they are encoded into working memory. Motor interference also seems unlikely, given that the responses are very simple and that the basic PRP effect is relatively insensitive to the similarity of the two motor responses (Pashler, 1994). Accordingly, the most likely stages for this interference would appear to be the intervening stages of target categorization (i.e., categorizing the stimuli according to the rules of the task) and response selection (i.e., mapping stimulus categories onto

responses according to the rules of the task). To distinguish between these two possibilities, it is possible to examine the latency of the P3 wave, which can differentiate between stimulus categorization and response selection.

When a subject is instructed to discriminate between two or more stimulus categories, the P3 wave is typically larger for relatively improbable stimuli than for relatively probable stimuli (see review by Johnson, 1986). As an example, consider a task in which subjects view a sequence of names and must indicate whether each name is used for males or for females (e.g., John vs. Sue). If each name is presented once, but 90% of the total are male names and 10% are female names, then a larger P3 wave will be elicited by the female names. The P3 wave is thus sensitive to the probability of a task-defined category, not the probability of an individual stimulus. Accordingly, an effect of probability on P3 amplitude cannot occur until the subject has determined the task-defined category of the stimulus, and the latency of the P3 wave is therefore highly sensitive to the amount of time required to perceive and categorize a stimulus (McCarthy and Donchin, 1981). In contrast, P3 latency does not vary when the difficulty of response selection is manipulated (Kramer, Wickens, and Donchin, 1983; Magliero et al., 1984). Thus, P3 latency can be used as a relatively pure measure of the amount of time required to perceive and categorize a stimulus.

To test the hypothesis that the slowing of responses at short SOAs in the PRP paradigm reflects a delay in response selection, the P3 wave was examined in the paradigm illustrated in figure 47.9A (Luck, 1998). T1 was an outline square, and the subjects were required to press one of two buttons with one hand to indicate whether the square was red or green. T2 was a letter, and the subjects pressed one of two buttons with the other hand to indicate whether it was an X or an O. To elicit the probability-sensitive P3 wave, one of the two T2 alternatives was presented less frequently than the other (25% versus 75% of trials). The P3 wave was then isolated by constructing infrequent-minus-frequent difference waves. This subtraction eliminated any ERP activity that was unrelated to the probability of T2, including T1-elicited ERP activity. If the slowing of the response to T2 at short SOAs in the PRP paradigm is caused by interference in perception or categorization, then the latency of the P3 wave should also be delayed at short SOAs. In contrast, if the slowed RTs are caused by interference with response selection, then the P3 wave should not be delayed.

The results of this experiment are summarized in figure 47.9B. As in previous PRP experiments, the RT for T2 was significantly slowed at short SOAs. In contrast,

FIGURE 47.9 Stimuli (A) and results (B) from an experiment in which ERPs were recorded during a PRP task. On each trial, a red or green outline square was presented, followed by an X or an O, and subjects were required to make speeded responses to both stimuli. One of the T2 alternatives was presented less frequently than the other so that a robust P3 wave would be elicited. Reaction times decreased sharply as the SOA between T1 and T2 increased, and the same effect was seen for both rare and frequent T2 stimuli. In contrast, P3 latency decreased only slightly, indicating that the prolonged RTs observed at short SOAs are a consequence of interference at a relatively late stage of processing, probably response selection. (Adapted with permission from Luck, 1998.)

P3 latency was only slightly delayed at short SOAs, which indicates that the slowing in RT reflects interference at a stage that follows perception and categorization, presumably response selection. A follow-up experiment showed that manipulations of T2 luminance produced large changes in P3 latency, demonstrating the sensitivity of the P3 wave to manipulations of stimulus evaluation processes. Thus, it appears that the slowing of reaction time in the PRP paradigm is due primarily to delays in response selection, which is consistent with the model of Pashler (1994).

Conclusions

For several decades, cognitive psychologists have debated whether attention operates at an early stage or at a late stage, but it is now becoming clear that attention operates at both early and late stages (and at intermediate stages, as well). Moreover, attention researchers are now beginning to understand the specific reasons why atten-

tion may be necessary at a given stage under a given set of conditions. In this chapter, we have identified two computational problems—the binding problem and the problem of internally generated noise—that provide good explanations of why attention is necessary at the stage of visual perception under some conditions but not under others. We have also pointed out two key limitations at the stage of working memory—the limited storage capacity and the slowness of the storage process. Presumably, attention will operate at the stage of working memory whenever these two limitations may impair task performance. Finally, we have provided evidence that attention may sometimes be required at the stage of response selection, although it is not yet clear why it is not possible to select different responses in parallel. It seems likely that attention operates at other stages of processing in addition to those discussed here and that the coarsely defined stages described in this chapter can be subdivided more precisely. A major challenge for the future is to determine how these multiple attentional mechanisms operate in a coordinated manner to maintain unity of behavior (Posner and Petersen, 1990).

ACKNOWLEDGMENTS Preparation of this chapter was supported by grants from the National Institute of Mental Health (MH56877-01 and MH25594-24), the Human Frontier Science Program (RG0136), and the Office of Naval Research (N00014-93-I-0942).

48 The Temporal Dynamics and Functional Architecture of Attentional Processes in Human Extrastriate Cortex

GEORGE R. MANGUN, AMISHI P. JHA, JOSEPH B. HOPFINGER, AND TODD C. HANDY

ABSTRACT Attentional processes in healthy human visual cortex can be investigated using electrophysiological and functional neuroimaging approaches. Each of these methods provides a unique view of brain activity. Electrophysiological recordings provide information about the time course and functional properties of brain processes, while functional neuroimaging provides detailed information about the anatomy of such processes. Used in conjunction, these methods permit valuable cross-constraints to be placed on the interpretations that can be derived from either method used alone. Here we review the logic of how event-related potentials (ERPs) and functional neuroimaging using positron emission tomography (PET) or functional magnetic resonance imaging (fMRI) can be integrated and applied to studies of human attention. In so doing, we provide evidence about the time course and functional architecture of early spatial selection processes, including how early stages of visual cortical analysis are influenced by voluntary and reflexive attention, and by spatial working memory.

The human ability to focus one's mind on sensory input, motor output, or internal thought relies on the coordination of a distributed set of attentional systems within the brain. Systematic observation of patients suffering from neurological damage has identified many of the key brain structures involved in attentional control (e.g., Luria, 1973; Mesulam, 1981); and, over the past few decades, cognitive neuropsychological studies have revealed much about the elementary cognitive operations that are supported by major brain attention systems (e.g., Posner et al., 1984). In recent years, powerful new tools have been developed that permit the cognitive activity of the human brain to be measured in healthy individuals. In particular, electrophysiological recording (e.g., Luck and Hillyard, chapter 47, this volume) and hemodynamic imaging (e.g., Chelazzi and Corbetta,

chapter 46, this volume) of neural activity have proved highly effective in investigating attentional mechanisms. In this chapter, we focus on how the *integration* of these methods offers new insight into the temporal dynamics and functional anatomy of human attentional processes.

Integrating ERPs and functional neuroimaging

Event-related potentials (ERPs), which are recorded from the scalp, are signal-averaged voltage fluctuations that are time-locked to sensory, motor, or cognitive events. As a research tool, ERPs are unsurpassed in revealing the time course of neural activity associated with the ERP-eliciting event, and have been invaluable in the study of attention and attentional processes (for reviews, see Mangun, 1995; Mangun and Hillyard, 1995). One long-standing question in attention research, for example, concerns how early in the afferent processing stream can attention modulate sensory input. Asking this question, a number of studies have now demonstrated unequivocally that cortical sensory processing is modulated as a function of whether a stimulus occurs at an attended location (see Luck and Hillyard, chapter 47, this volume). Evidence from ERPs provided strong clues regarding the time course of early attentional selection; however, these scalp-recorded measures provided little information about the neuroanatomical loci at which attention exerted influence on stimulus analysis. Identification of the neuronal generators of these and other scalp-recorded ERPs could therefore be an important step toward the goal of describing the functional architecture of attentional circuitry in the human brain.

Unfortunately, inferences about the intracranial neural generators of scalp-recorded ERPs, termed inverse modeling, are difficult to make. The difficulty stems, in part, from the "inverse problem"—the fact that any specific pattern of electrical activity recorded at the scalp might arise from more than one unique configuration of electrical currents flowing within the volume of the head

and brain (e.g., Dale and Sereno, 1993; Zhang and Jewett, 1994). One possible means of mitigating the limitations in inverse modeling is to constrain the numbers of possible solutions by using prior knowledge of anatomy or physiology. We have introduced methods that experimentally integrate electrical and blood flow measures to provide additional information about the functional anatomy of attentional processes in visual cortex. The simple idea is that functional imaging using PET or fMRI can help to identify regions of the brain that are active during specific sensory, motor, or cognitive processes. Inverse electrical (or magnetic) modeling may thus be constrained, hence permitting tests of a limited set of possible generators for scalp-recorded ERPs.

In our original study using PET, we found that spatial selective attention to one-half of rapidly flashed (3 per second) bilateral symbol arrays activated extrastriate visual cortex (posterior fusiform gyrus) in the hemisphere contralateral to the attended stimuli (Heinze et al., 1994). These PET activations were then used to determine the possible locations and numbers of active areas in our task. Modeling was used to ask whether electrical activity within the brain regions defined by PET activations during spatial attention could possibly have yielded our ERP effects. We used the BESA (brain electric source analysis) method developed by Michael Scherg and his colleagues (see Scherg, 1992). BESA models the head as concentric spheres of different conductivity, and neural activity contributing to scalp-recorded ERPs as equivalent current dipoles. The BESA program permits one to specify a three-dimensional location within the volume of the spherical model head where a dipolar electric source is to be located, then allows calculation of the predicted voltage on the surface of the model head. Accordingly, we placed dipoles within the model head at the locations where PET indicated attention-related activations had occurred. We referred to these models as “seeded-forward solutions,” because we placed (or seeded) the model neural sources (equivalent current dipoles) within the PET-defined brain loci. Using this approach, we argued that attention-related modulations of the sensory-evoked activity in visual cortex reflected changes in input processing in extrastriate visual cortex in the region of the posterior fusiform gyrus. Thus, for the first time, a cognitive operation (early attentional filtering) was localized both in time (80–130 ms poststimulus) and space (posterior fusiform gyrus) in the human brain.

Covariations in ERP and PET measures

Following up the study of Heinze and colleagues (1994), we investigated whether electrical (ERP) and blood flow

(PET) activations covaried across task manipulations (Mangun et al., 1997). The logic is that ERP and PET activities generated as the result of the same attentional processes should covary across conditions in which the allocation of spatial attention varies systematically. In order to vary the allocation of spatial attention, we manipulated *perceptual load*. Perceptual load has its conceptual roots in capacity theories of attention (see Kramer and Spinks, 1991). It follows from the notion that spatial attention can be likened to a limited-capacity resource that can be allocated to various spatial locations depending upon the perceptual demand created by the stimulus or task conditions (e.g., Lavie and Tsai, 1994; Lavie, 1995). Using ERPs, we have shown that perceptual load can affect the allocation of spatial attention at early stages of visual analysis (Handy and Mangun, in press). This suggests that as the perceptual load of a target item increases, more attentional resources are allocated to the spatial location of that target, leaving fewer residual resources for processing information in nontarget locations. Thus, manipulation of perceptual load offered a straightforward means of looking for covariations in ERP and PET measures of spatial attention.

In our study (Mangun et al., 1997), spatial attention effects were compared for a high-load condition similar to the symbol-matching task (see figure 48.1, top) used by Heinze and colleagues (1994), and for a lower load condition where subjects performed a simple luminance detection task. In the latter, “dot-detection” task, the target was a small dot stimulus (1 to 4 pixels, appearing anywhere within the area traversed by the symbols) whose onset was simultaneous with the symbol pairs. Lower perceptual load for the dot-detection task was demonstrated by a higher overall accuracy rate in behavioral performance in this condition relative to the more demanding symbol-matching task.

Independent of the specific task condition, focused attention to the left half of the arrays produced a PET activation in the right posterior fusiform gyrus, while attention to the right produced activation in the left posterior fusiform gyrus (figure 48.1). Additional activations in the contralateral middle occipital gyrus were also observed, but will not be discussed further here. Corresponding attention-related modulations of the P1 ERP component (110–140 ms) were observed over lateral occipital scalp regions contralateral to the attended hemifield. As the scalp voltage map of figure 48.1 indicates, the attention effect in the latency range of the P1 was sharply focused over scalp regions that overlie lateral extrastriate cortex, consistent with evidence from previous studies (e.g., Mangun, Hillyard, and Luck, 1993; Heinze et al., 1994).

However, of particular interest in this study was what differences, if any, would be observed as a function of

perceptual load. Specifically, would the PET and ERP measures covary with the load-related manipulations of spatial attention? In order to address this question, the statistical interaction between the direction of attention (attend left vs. attend right) and task (symbol matching vs. dot detection) was evaluated. Attention effects in the fusiform gyri showed a statistically significant interaction of task and attention, with greater attentional activations during the difficult symbol-matching task than during the dot-detection task (figure 48.1). Importantly, this pattern was paralleled by the findings for the P1 ERP component, where the attention effect was significantly larger for symbol (high load) than for dot (low load) conditions (figure 48.1 shows the interaction in the P1). This covariation of the P1 attention effects and the fusiform gyrus PET activations can be interpreted as additional evidence that the P1 effect is actually generated in the fusiform gyrus, and converges with prior ERP data (e.g., Mangun and Hillyard, 1991) indicating an early locus of spatial attention effects on visual processing.

Mapping multiple attention-sensitive areas

The integration of ERPs and PET has helped to define the functional anatomy of early attentional modulation of stimulus inputs by providing evidence about the anatomical regions of the human brain in which attention can influence information processing. However, knowing, for example, that the posterior fusiform gyrus is activated by spatial attention tasks does not help us relate such activity to the current knowledge about the functional organization of the primate visual system derived from single-cell recordings in monkeys. That is, single-unit recordings in monkeys have identified numerous successive retinotopically organized maps (areas) of visual space in visual cortex (e.g., Felleman and Van Essen, 1991). These visual areas contain neurons that code different aspects of visual inputs, and thus it is important to identify which of these functionally defined visual areas can be influenced by attention and which cannot. In monkeys, these areas include maps for lower visual field regions projecting dorsally in the brain, beginning with V1 (striate cortex) and continuing with successive re-representations including V2 and V3 (second and third visual areas, respectively). For upper-field stimuli, the maps from V1 project ventrally toward inferotemporal lobe from V1 to V2, VP, and ventral V4 (V4v).

Functional neuroimaging is now being used to identify analogous visual cortical areas in humans, and the results are showing highly similar patterns of visual cortical organization between the macaque and human—despite critical differences in the underlying gross anat-

omy (e.g., Zeki et al., 1991; Engel et al., 1994; Sereno et al., 1995). In order to relate the PET activations reported above to these functionally defined visual areas, we have recently performed functional magnetic resonance imaging (fMRI) in single subjects. We first mapped the borders of the early visual areas (e.g., V1 and V2) in each of our subjects by stimulating the vertical and horizontal meridia of the visual field with a reversing checkerboard pattern. The activations in occipital cortex were then mapped onto anatomical templates that were derived from high-density anatomical scans of each subject (figure 48.2). The borders of V1, V2, VP, and V4v were identified as the locations where the visuotopic mappings reached either the vertical or horizontal meridian and reversed direction. Thereupon, the functionally defined visual areas were assigned using the “sign” method of Sereno and co-workers (1995).

During the same recording session, the subjects also performed the symbol-matching task used in the PET experiment discussed above, in which attention-related activations were found in both the fusiform and middle occipital gyri. Adapting the task to fMRI, subjects were instructed to attend to a location in one hemifield for a 16-s block; then in response to a visual arrow cue, they were required to switch attention to the other hemifield for 16 s. Attention was alternated between hemifields in this fashion for the duration of the ~4-min scanning period, with stimuli presented bilaterally at a rate of about three per second. Attention to upper- and lower-field stimuli was examined in separate scanning runs. Here, however, we discuss only the data for the upper visual field stimuli in order to compare the results directly with our prior PET (Heinze et al., 1994; Mangun et al., 1997) and fMRI (Mangun et al., 1998) studies. To identify which specific areas of cortex were modulated by attention, the functional scans from this task were coregistered with the anatomical templates described above, as shown in figure 48.2.

For the upper visual field stimuli, the attention-related fMRI activations were localized to the contralateral posterior lingual and fusiform gyri, and the inferior and middle occipital gyri. Although prior studies failed to identify the precise visual areas (e.g., V4v) generating these attentional modulations, the method of retinotopic mapping used in our study reveals that these extrastriate attentional activations occurred in areas V2, VP, and V4v, as can be seen by comparing the left and right halves of figure 48.2. In addition to providing key information about the stages of visual processing modulated by voluntary spatial attention, these data also provide important constraints for future dipole modeling of attention-sensitive ERP generators. That is, activations in separate visual cortical maps can now be modeled as

FIGURE 48.1 PET activations overlaid onto coronal sections of MRI scans, and scalp topographic voltage maps of attention effects. The task was to view bilaterally flashing stimulus arrays (top) and, while maintaining fixation on the cross-hairs, to covertly attend to either the right or left stimulus location (ignoring the opposite hemifield) in order to detect infrequent targets stimuli (matching symbols, in the symbol discrimination task; a small dot within the symbols in the dot-detection task). The main effects (collapsed across the perceptual load manipulation) of spatial selective attention (middle) included activations in the contralateral posterior fusiform (outlined in black). For example, attending to the right half of the arrays produced activations in the left occipital lobe (left of figure), while attending to the left produced activations in the right hemisphere (right of figure). (Note that the left hemisphere is on the left of each brain in the figure.) The ERP effect, shown in the center of the figure as a voltage topographic map over the period from 110–140 ms after stimulus onset, is the subtraction of the attend-left minus the attend-right voltage maps. The P1 attention effect is seen as the bilateral foci in each hemisphere. (Note that the apparently opposite polarity of the left and right hemisphere electrical effects is due to the direction of the subtraction; i.e., both foci actually represent contralateral enhancement of the positive polarity P1 component). At the bottom are shown the loci of brain activation where the attention effects interacted with the perceptual load manipulations. These fell within the posterior fusiform region. As predicted for a P1 effect generated in the posterior fusiform, the P1 effect also varied with perceptual load. Thus, there was a difference between the symbol and dot discrimination tasks in the amplitude of the P1 attention effect; this is shown in the difference map at bottom (P1 attention topographic map in the symbol condition, minus the map in the dot detection condition). Note that the P1 attention effect also showed a maximal difference as a function of perceptual load at the same occipital scalp loci that were found for the main effect of attention (compare bottom topographic map to top map). (Data adapted from Mangun et al., 1997)

distinct electrical generators, rather than as a single neuroelectric source.

Reflexive orienting and spatial attention

So far, we have outlined the temporal dynamics of early attentional processing in the brain, as well as the neuroanatomical substrates underlying these effects in extrastriate visual cortex. However, our discussion has focused on *endogenous* attentional orienting—i.e., attentional processes that are under voluntary control. In this section, we turn to reflexive or *exogenous* attention (see Posner and Cohen, 1984). Unlike voluntary attention, which reflects the purposeful allocation of attention by a willing subject, reflexive attention is associated with external events that automatically “capture” attention, such as the abrupt or sudden onset of a transient visual stimulus (e.g., Yantis, 1996).

The fundamental differences between voluntary and reflexive attention have engendered speculation that re-

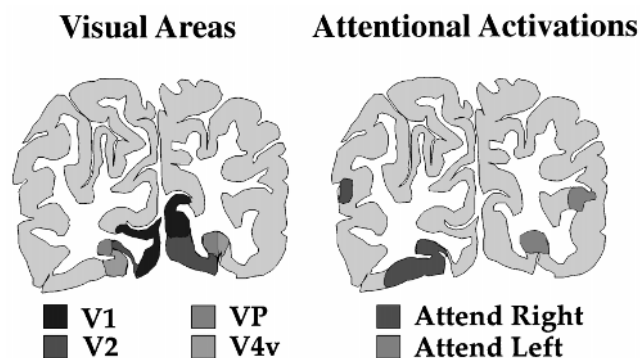

FIGURE 48.2 The visual activations from the meridian stimulation were used to determine the borders of the early occipital visual areas. One representative subject's functionally defined visual areas (V1, V2, VP, and V4v) are depicted on the left. The functionally defined visual areas are overlaid on anatomical templates for this subject that were constructed from anatomical MRI scans. On the right, the attentional activations in the same subject for the same slice are shown. The attentional activations occur in multiple visual areas including V2, VP, and V4v, as well as outside these areas in the inferior and middle occipital gyri.

flexive attention might be controlled—either wholly or in part—by neural mechanisms distinct from those involved in voluntary attention (e.g., Kustov and Robinson, 1996; Rafal, 1996; Robinson and Kertzman, 1995). However, whether the *effects* of voluntary versus reflexive attention on early visual processing are comparable remains an open question. That is, as shown above, voluntary visual-spatial attention involves a modification of cortical sensory processing, leading to a relative facilitation in visual processing in extrastriate visual cortex by 70–80 ms poststimulus (e.g., Eason, 1981; Heinze et al., 1994; Luck et al., 1994; Mangun and Hillyard, 1991; Van Voorhis and Hillyard, 1977). Are there, then, similar changes in the perceptual processing of visual stimuli as a result of reflexive shifts of attention?

Recently, we demonstrated that reflexive attention can indeed modulate early visual processing at the same neural locus as voluntary attention (Hopfinger and Mangun, 1998). In our study, targets were preceded by an uninformative flash (the cue) either at the same location (cued-location target) or at a location in the opposite hemifield (uncued-location target). Importantly, the subjects knew that the cue was completely uninformative of the location of the upcoming target, and therefore did not invoke any voluntary orienting in response to the cue. Two different cue-to-target inter-stimulus interval (ISI) ranges were used in order to measure the rapid and changing time course of reflexive attention. Both a short ISI of 34–234 ms and a long ISI of 576–766 ms were used; however, only the short ISI results are discussed here. In order to disentangle the brain responses to the

Reflexive Attention - Short ISI

cue from those to the target, especially important for the short ISI condition, the Adjard filter developed by Woldorff (1993) was employed. This method estimates the contamination of an ERP by electrical potentials from prior or subsequent stimulus or response events, and permits the contamination to be removed.

Targets at a recently precued location elicited visual ERPs with significantly enhanced amplitudes compared to targets at an uncued location (figure 48.3, top). This enhancement was observed for the occipital P1 component. By investigating topographic voltage maps during the time period of the P1 component, it was

FIGURE 48.3 Top: Event-related potentials (ERPs) to lateralized target stimuli over the contralateral occipital scalp site where the P1 component was of maximum amplitude. The trace shown is averaged over left occipital site (OL) for right-field stimuli, and right occipital site (OR) for left-field stimuli. OL and OR are located midway between T5 and O1, and T6 and O2, respectively, of the International 10-20 system of electrode placement (Jasper, 1958). The shaded gray box indicates the P1 latency range (90–140 ms). For the short cue-to-target ISI condition, cued-location targets (solid line) elicited a significantly enhanced P1 component compared to uncued-location targets (dotted line). Bottom: Scalp topographic voltage maps, presented on rear view of the head and referenced to the right mastoid, showing attention effects at the peak of the P1 component (110–120 ms latency range). ERPs elicited by left visual field targets are presented on the left; ERPs elicited by right visual field targets are presented on the right. Cued-location targets (above) produced enhanced P1 peaks compared to uncued-location targets (below). The small black dots on each topographic map indicate the location of the electrodes. The positive maxima of each map are shaded. (Adapted from Hopfinger and Mangun, 1998.)

possible to see that the location of the maximal response at the scalp corresponding to the P1 component was highly similar for cued- versus uncued-location targets (figure 48.3, bottom). This pattern is consistent with the view that the same neural process was invoked in both cases, the primary difference being the strength of the response. The occipital P1 component represents the earliest stage of visual processing to be reliably modulated by *voluntary* spatial attention (e.g., Heinze et al., 1994; Mangun, 1995; Mangun and Hillyard, 1991). The present findings indicate that although separate control circuitry may be involved, reflexive attention leads to modulations at this same stage of visual cortical processing.

Working memory and spatial attention

In a voluntary attention task, attending to a specific location requires remembering—during the interval preceding a target—which location is task-relevant (i.e., where to attend). Spatial working memory refers to this ability to temporarily store and manipulate spatial information over brief periods of time. An area of increasing interest to researchers of both attention and memory is the possible relationship between spatial attention and spatial working memory processes. In this section, we discuss how the identification of cortical areas labile to modulation by spatial attention, as measured by ERPs and localized using functional neuroimaging, has provided novel insight into this issue.

Recent neuroimaging evidence suggests that there may be an overlap in the functional circuitry subserving spatial attention and spatial working memory. Frontal,

parietal, and extrastriate areas have been observed to be active during both of these cognitive operations (Jonides et al., 1993; McCarthy et al., 1996; Owen, Evans, and Petrides, 1996). In addition, recent behavioral studies have suggested that holding a location in working memory imparts a perceptual advantage to stimuli occurring there, something typically attributed to the benefits of selective attention. That is, when stimuli were presented to a location being maintained in working memory, they were responded to with greater speed and accuracy than when those stimuli were presented at other locations (Awh et al., 1998). Both the behavioral evidence and the neuroimaging evidence have led to the hypothesis that one maintains information about locations in working memory by selectively attending to those regions of space. If this is indeed true, then the activations observed in occipital cortex during spatial working memory tasks could be interpreted as analogous to those observed when subjects are required to selectively attend regions of space. We have tested this proposal using ERPs (Jha and Mangun, 1998).

As described above, voluntary spatial attention begins to affect visual processing as soon as 70–110 ms after the initial appearance of the stimulus, affecting the occipital P1 component—an especially well-understood attention-sensitive ERP (e.g., Mangun, 1995). If selective attention is involved in the maintenance of location information during spatial working memory, then the P1 component should be larger in amplitude for stimuli presented at a to-be-remembered location than for stimuli presented elsewhere. Additionally, if any such effects are found in the ERPs, it would be possible to ask whether the activity persisted throughout the period that working memory was maintained (the memory delay period). For example, if attention is required only for encoding the to-be-remembered location, attention-like modulations should be observed only for stimuli presented shortly after a memory cue, when encoding presumably takes place (Jones et al., 1995; Jones and Morris, 1992; Toms, Morris, and Foley, 1994).

To provide a measure of whether attention is involved in the maintenance of information in working memory, task-irrelevant probe stimuli were presented during the 4.8–5.3-s memory interval of a spatial working memory task. Subjects were informed that the probes were irrelevant to the task and were instructed not to respond to these stimuli. The probe followed the memory cue, with a stimulus onset asynchrony (SOA) of either 400–800 ms or 2600–3000 ms. Probe stimuli have been used in several studies of spatial attention as a means of sampling the distribution of attention, and have been found to elicit enhanced-amplitude P1 components when appearing at an attended location, even

ERP Responses to Probes

FIGURE 48.4 ERP responses to probe stimuli collapsed across the 6 possible probe locations. The contralateral ERP response is plotted for the lateral occipital electrode sites (OL/OR). The time range of the P50-100 effect is highlighted by shading. The y-axis is the microvolt value (range -2.0 to 2.0 microvolts) and the x-axis is the time epoch (0-400 ms). Probe

onset is at the upright calibration bar. The P50-100 effect was larger for probes occurring at locations being held in working memory than when the probes occurred elsewhere in the visual field, and this was true at both SOAs. Below the ERPs are bar graphs depicting the microvolt value for the time period of the P50-100 effect for congruent and noncongruent probes.

when the probes are task-irrelevant (e.g., Heinze and Mangun, 1995).

Subjects were very accurate (90% correct, mean RT = 599 ms) in performing the memory task. Probe stimuli presented at the location congruent with the to-be-remembered location (congruent condition) elicited significantly ($p < .01$) larger occipital positive responses from the 50-100 ms latency than did probes at non-memorized (noncongruent condition) locations (figure 48.4). Because the relationship between this *spatial working memory effect*, and the *P1 attention effect* remains unclear at present, we will refer to the working memory effect using a polarity (P for positive polarity) and latency (50-100 ms range) nomenclature; that is, as the P50-100 effect. This P50-100 effect was observed both for probes presented at the short SOA and the long SOA. The P50-100 pattern is precisely that predicted for spatial attention focused on the memory location prior to the onset of the probe stimulus, and maintained there

throughout the delay period. Interestingly, there was also a significant amplitude enhancement in the N1 latency range from 160-180 msec.

To the extent that the P50-100 effect for spatial working memory reflects processes similar or identical to the P1 attention effect, the current ERP results suggest that the observed overlap in brain areas activated during spatial attention and spatial working memory tasks reflect a reliance on the same neural hardware. Previous single-unit studies of object working memory, for example, have suggested a similar relationship for object working memory and attention during visual search operations. That is, object working memory is needed to keep relevant object information active so that while many objects are in view, an attentional search for the relevant object will be facilitated (Chelazzi and Desimone, 1994; Chelazzi et al., 1993). A similar type of interdependence between working memory and attentional mechanisms may exist for spatial working memory.

Summary

In this chapter, we have reviewed a number of studies that investigated attentional and working memory processes using ERPs and functional neuroimaging. Both voluntary and reflexive attention were shown to modulate visual information processing at early stages. Holding a location in working memory also leads to changes in visual cortical processing, and in a manner that suggests a close relationship between spatial attention and spatial working memory during visual processing. Furthermore, these effects in visual cortex can be localized anatomically and related to functionally defined regions of extrastriate visual cortex using functional neuroimaging in combination with ERP recording. By integrating ERPs and functional imaging methods, the time course and functional anatomy of cognitive processes can be revealed with a higher resolution than has previously been possible. Although new methods are always, thankfully, lurking around the corner, the integration of electromagnetic and functional neuroimaging approaches will no doubt continue to reveal a unique view of the thinking human brain for the foreseeable future.

49 Networks of Attention

DAVID LABERGE

ABSTRACT Attention is assumed to be expressed by the amplification of neural activity in particular clusters of cortical columns. The network that produces the expression of attention involves a neural amplification mechanism and structures that control this mechanism from both top-down and bottom-up directions. This chapter reviews recent neurobiological studies that indicate that attention-related neural activity increases in regions of the brain that correspond to the expressions, mechanisms, and controls of attention. These regions are distributed widely across the brain and are assumed to be interconnected by a triangular network, which produces activity simultaneously in these three regions when an attention event occurs.

The selective function of attention is assumed to be manifest in three main forms, according to one view (Laberge, 1995a): simple selection, preparation, and maintenance. Simple selection is typically brief in duration, as in searching displays and reading words, and its immediate goal usually is the identification of the selected information. In preparatory attention, attention to a selected object, attribute, or spatial location is sustained over a preparatory period of time (e.g., between a cue and a target), and the goal is to respond more effectively to the anticipated stimulus event; this preparatory process often involves the imaging of the object or attribute. Maintenance attention refers to cases in which attention to a selected entity is sustained over a period of time, but the goal is the processing of the ongoing activity for its own sake; examples of this “appreciating” activity are tasting a wine, listening to music, and feeling sadness or joy.

The plan of this chapter is first to review the evidence regarding the following issues related to the selective operations of attention: (1) how attention carries out, or expresses, the selective operation in cortical columns; (2) discovering the brain structures that modulate the cortical expression of attention; and (3) determining the brain structures that control what is selected. Finally, a model will be described in which a triangular circuit interconnects the brain sites serving the expression, modulatory mechanism, and control operations that together are presumed to produce an attentional event.

The expression of attention

The codes or representations that are activated into perceptions, images, ideas, feelings, and actions appear to reside within columns of the neocortex. It is commonly assumed that the cortex is organized in columnar fashion (Mountcastle, 1957; Szentágothai, 1975) and that the cognitive properties of brain function are produced not by single neurons but rather by the combined interactions of neurons within the columnar circuitry.

The selective property attention is presumed to be expressed by a positive difference between the activity levels in columns that code for the target and the activity levels in neighboring columns that code for other (distracting) objects. This difference in activity levels can be produced in three ways: by enhancement of the target site, by suppression (or decay) at the distractor site(s), or by both operations. Figure 49.1 presents a simplified schematic description of the average firing rates of

Stimulus Display

Target (T) and Distractor (D) Trajectories

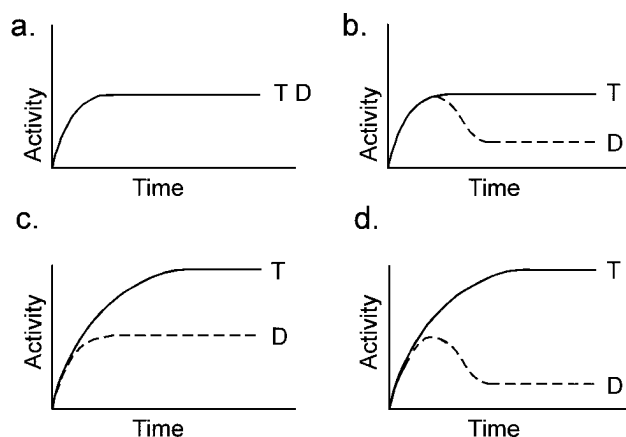

FIGURE 49.1 Schematic diagrams of three ways that selective attention to a target *T* presented near a distractor *D* can be expressed by activity in corresponding cortical columns (shown in b, c, and d). The stimulus-induced activity of both target and distractor sites is represented in a.

neurons in cortical columns coding a target item and a distractor item placed somewhere within the visual field.

In the early moments following display onset, cells in the column sites serving each item increase their activity in response to sensory input. If attention were directed to neither item or to both items, the trajectories would presumably take the form shown in figure 49.1a (with the attention-to-both case showing higher asymptotes and later declines). If one item becomes the target of attention, then the activities at the target and distractor sites diverge, and this divergence assumes one of the forms shown in figures 49.1b, c, and d. If attention to the target item is induced prior to the display (in the preparatory mode of attention), then the trajectory for the target in these three figures is displaced upward away from the trajectory for the distractor, and selective attention within the display undergoes a “head start.”

In the psychological literature, selection by a target-enhancement operation has been implicitly assumed in the use of the metaphors of spotlight, zoom lens, capacity allocation, and gain, while the distractor-suppression operation has been implicit in the use of the terms filter, gate, and channel. Three psychological theories of selective attention, over two decades old, that embody either suppression or enhancement are represented schematically in figure 49.2. Figure 49.2a represents complete filtering of sensory input from distractors (Broadbent, 1958); figure 49.2b represents attenuated filtering of sensory input from distractors (Treisman, 1960); and figure 49.2c represents the enhancement of sensory input from the target (LaBerge and Samuels, 1974). The activity level at the target site in figures 49.2a and 49.2b is driven by retinal stimulation only, while in figure 49.2c it is also driven by internal, top-down sources.

Top-down influences on retina-driven activity apparently are carried by excitatory fibers by way of direct corticocortical projections or by way of indirect projections that synapse first in a thalamic nucleus (Jones, 1985; Salin and Bullier, 1995). These fibers apparently terminate mainly on excitatory neurons in cortical columns (Johnson and Burkhalter, 1996) where attention is expressed. Therefore, top-down selection would appear to be expressed predominantly by the enhancement of activity at the target site (or by decay of activity at the distractor sites) in extrastriate cortex. A theoretical description of bottom-up selection by distractor suppression, involving inhibitory influences within oculomotor mechanisms, is given elsewhere (LaBerge, 1995b, 1997b).

The mechanisms of attention

When target selection is characterized by an enhancement of activity in a specific set or cluster of cortical

FIGURE 49.2 Schematic diagrams of selective attention operations according to some theories of attention in the psychological literature. (a) Complete suppression at distractor sites (Broadbent, 1958); (b) attenuated suppression at distractor sites (Treisman, 1960); (c) enhancement at the target site (LaBerge and Samuels, 1974). The arrows pointing from right to left represent controlling signals that select the part of the sensory input to be attended.

columns, where are the neural circuits that produce that enhancement? One possible location is within the cortical column itself, in which there exist a sufficient number of feedback connections to produce significant self-amplification (Douglas et al., 1995). Cortical self-amplifying circuits could be triggered or regulated by signals from sources outside the immediate cortical areas—for example, by fibers arising from the prefrontal cortex or from the thalamus.

Other possible locations of an amplifying circuit lie outside the cortical column. One possible external source of attentional amplification is the set of neuromodulatory cells in the brain stem and basal forebrain, whose axon fibers spread diffusely across large areas of cortex. These neuromodulatory centers regulate the state of wakefulness and states of alertness (Steriade, McCormick, and Sejnowski, 1993), which themselves are preconditions for states of attention. However, the distribution of these fibers to cortical columns is too diffuse to produce the differences in patterns of neural activity required for separation of target and distractor activities,

FIGURE 49.3 Activity increases indicated in three thalamic nuclei (pulvinar, mediodorsal, and ventrolateral) when a hard identification task was compared with both an easy identification task and a control task (right thalamus), and when the easy task was compared with a control task (left thalamus) (Liotti, Fox, and LaBerge, 1994).

particularly when they are spatially close in visual displays (e.g., figure 49.1).

Another possible external source of attentional amplification is the thalamus, which is known to contain circuits that reciprocally project to cortical columns in the form of thalamocortical loops. The thalamocortical loop receives axon fibers (at the relay neuron) from neurons in other brain areas (Conley and Raczkowski, 1990; Ungerleider, Galkin, and Mishkin, 1983; Schiller, 1984), so that the thalamocortical loop may be driven directly by both bottom-up sources of sensory control (e.g., from V1 and superior colliculus) and top-down sources of voluntary control (from the prefrontal cortex).

The thalamus is connected reciprocally with virtually every area of cortex (Jones, 1985), and therefore tha-

lamic nuclei have the capability of influencing activity levels in any cortical area. Of particular interest in this chapter is the pulvinar nucleus, which projects reciprocally to visual areas in the occipital, temporal, parietal, and frontal lobes. In the human, the pulvinar is the largest nucleus of the thalamus, occupying approximately two-fifths of the thalamic volume. The proportional size of the pulvinar to the thalamus decreases from human to monkey, and in the cat the pulvinar is so small that it escapes labeling in many brain atlases. Within the primate pulvinar are four major divisions termed the *medial*, *lateral*, *inferior*, and *anterior* pulvinar (Jones, 1985).

The pathways of early visual processing in both cortex and superior colliculus interconnect with the pulvinar in a manner that preserves topographical relations, particularly with the inferior and lateral nuclei of the pulvinar (Burton and Jones, 1976; Petersen, Robinson, and Keys, 1985). In the posterior parietal areas, neurolabeling studies have shown connections from LIP and 7a to PuL and PuM and vice versa (Romanski et al., 1997; Schmammann and Pandya, 1990). The PuM also connects reciprocally with lateral prefrontal areas (Romanski et al., 1997). The regions within PuM containing cells that connect to area 7a apparently overlap areas in PuL containing cells that connect with the lateral prefrontal area (Asanuma, Andersen, and Cowan, 1985) and with regions in the temporal lobe (Webster, Bachevalier, and Ungerleider, 1991). Therefore, reciprocal connections exist between parietal and temporal areas and the pulvinar, and also between lateral prefrontal areas and these pulvinar areas.

The neurons of the pulvinar form thalamocortical loops with the visual areas of the posterior cortex, and these neurons have well-defined receptive fields that are less than a degree in size near foveal center and increase in size as eccentricity increases (Bender 1981; Petersen, Robinson, and Keys, 1985). The size-eccentricity relationship of these pulvinar neuron receptive fields is quite similar to the size-eccentricity relationships of V1 and V2 cortical cells (Gattass, Gross, and Sandell, 1981). In view of the sensitivities of these neurons to small changes in visual locations of an object, it would not seem unreasonable to view pulvinar neurons as occupying a seventh layer of the visual cortex. This close relationship between thalamic neurons and cortical columns would appear to generalize to the rest of the neocortex.

The participation of the pulvinar in visual attention tasks has been proposed by several theories (e.g., LaBerge, 1990; LaBerge and Brown, 1989; Olshausen, Anderson, and Van Essen, 1993; Posner et al., 1988) and supported by the findings of a variety of neuroscience studies. Human patients with lesions in the posterior thalamus showed deficits in responding to cued

and uncued locations of visual stimuli contralateral to the lesion, while showing no evidence of contralateral neglect (Rafal and Posner, 1987). Rafal and Posner interpret these findings as indicating an impairment in engaging attention at a new spatial location in contrast to the impairment in disengaging attention from a currently attended location, which is characteristic of the neglect syndrome typically produced by lesions in the posterior parietal areas (e.g., Posner et al, 1984). In monkeys, lesions in the pulvinar produce impairments in the attentional scanning of a visual display (Ungerleider and Christensen, 1979).

Single-cell studies indicate that pulvinar neurons increased their firing rates to a visual stimulus when that stimulus is a target of an impending eye movement or when the animal simply attends to it without a subsequent eye movement (Petersen, Robinson, and Keys, 1985). When microinjections of mucimol, a GABA agonist, were injected into the dorsal region of the medial pulvinar of monkeys, shifts of attention to the contralateral visual field were impaired in a spatial orienting task; injections of the GABA antagonist bicucilline into the same area facilitated shifts of attention to the contralateral visual field (Petersen, Robinson, and Morris, 1987).

A variety of PET studies of experiments with humans have shown activation of the pulvinar during visual attention tasks, and in an earlier review of the available evidence (LaBerge, 1990) it was proposed that the details of the thalamocortical circuit indicate that it embodies an algorithm that enhances firing in a target set of cortical cells while inhibiting firing in the surrounding set of cortical cells. Corbetta and colleagues (1991) used a task that focused attention in preparation for discriminating among an array of stimuli with respect to their shape, color, or velocity of movement, and found an increase in blood flow in the right thalamus during the velocity and shape conditions. Another PET study (LaBerge and Buchsbaum, 1990) used a task designed to strongly intensify the activity brain structures involved in selectively attending to a shape, by asking subjects to identify a briefly presented target shape *O* (versus a *C* or a zero) when the target was surrounded on all sides by eight similar characters (*G* and *Q*). The target display was presented in the same location during a block of trials (to the right or left of a central dot), and the 1400-ms interstimulus interval allowed time for the subject to increase preparatory attention to a level necessary to identify the briefly flashed target. The PET results showed a significant increase in the pulvinar, and it appeared that all of the increase was in the right pulvinar.

Using the same concentrated attention task of the LaBerge and Buchsbaum (1990) experiment (with a cue-target preparatory interval of 1600 ms), Liotti, Fox, and

LaBerge (1994) added an easy task (the *O* surrounded by slanted lines) and a control task, and found a strong and significant increase in the right pulvinar for the hard task (see figure 49.3). Two other thalamic regions showed increases in activation when the hard condition was compared with the easy and control conditions. One activated thalamic region contained the mediodorsal nucleus, which connects strongly with the prefrontal cortex and also with the parietal cortex; this region was also activated in the Corbetta and colleagues (1991) study with shapes and in the Heinze and colleagues (1994) study in which subjects sustained focal attention on locations in the right visual field. The third thalamic region activated by the hard task in the Liotti, Fox, and LaBerge study was the ventrolateral nucleus, which connects with both the frontal areas and the basal ganglia. Corbetta and colleagues (1991) found activations in this region when subjects shifted attention toward the right in the right visual field. Thus three regions of the thalamus appear to be selectively active when humans are attending to visual shapes and their locations.

The Liotti, Fox, and LaBerge (1994) study also showed that increased activations in the three thalamic nuclei during the hard task are correlated with cortical regions that are directly connected with these three thalamic nuclei. Activations of the right pulvinar correlated with activations in the right and left fusiform gyrus; activations of the mediodorsal nucleus correlated with activations of the right ventrolateral prefrontal cortex; and activations of the right ventrolateral nucleus correlated with the right ventrolateral prefrontal cortex and the right head of the caudate nucleus of the basal ganglia. The prefrontal areas and the basal ganglia may control what will be attended to and how intensely. This issue will be addressed in the next section of this chapter concerned with the control of attention.

Other recent studies support the involvement of the thalamus in attention. Frith and Friston (1996) showed that the right midthalamus was activated when subjects were attending to sounds while ignoring visual stimuli. Morris, Friston, and Dolan (1997) found that increases in salience of emotionally expressive faces increased activation in the right pulvinar nucleus. Shulman and colleagues (1997) analyzed nine PET studies of visual processing, which included tasks of discrimination, search, language, memory, and imagery. Taken together, the nine tasks showed no common cortical regions of activations (outside of V1) but did show consistent activation in the thalamus and the cerebellum. In particular, the activated region of the right thalamus appeared to spread over several nuclei. The activations in the right and left thalamus were not correlated, suggesting that they serve different functions.

FIGURE 49.4 The thalamocortical circuit of virtually all cortical areas. Afferent fibers (e.g., from the frontal cortex) synapse on dendrites of the relay cell near the soma, and axons of the relay cells project mainly to middle layers of a cortical column. Fibers from Layer 6 of the cortical column synapse mainly on distal dendrites of the relay cells.

One way to determine the suitability of a proposed mechanism for producing the expression of selective attention in cortical areas is to examine its circuitry and then evaluate its potential for producing the output firing patterns that resemble one of the selection trajectories shown in figure 49.1.

THE STRUCTURE OF THE THALAMOCORTICAL CIRCUIT Figure 49.4 shows a diagram of the types of cells in the thalamic and cortical part of the circuit, along with their known pattern of interconnections. The only uncertainty about the connectivity concerns whether the reticular nucleus projects its axons to relay cells lying only within a thalamic column (e.g., Crick, 1984; Steriade, Domich, and Oakson, 1986), or to relay cells lying only in neighboring columns (e.g., Sherman and Koch, 1986), or to both (LaBerge, Carter, and Brown, 1992). According to simulations of a network model of the thalamocortical circuit (to be described later in this section), all three patterns of connectivity produce the mode of attentional expression shown in figure 49.1D. Although almost all of the available cellular and connectivity knowledge about the thalamus is based on the monkey, cat, and rat, it appears to be relatively safe to extrapolate from monkey to human

because the monkey and human thalami show identical histochemical staining patterns (Hirai and Jones, 1989).

A thalamic nucleus is organized in a columnar manner, in the sense that the flow of impulses from an afferent input through a thalamic relay cell is segregated from the impulses flowing through other thalamic relay cells (Jones, 1985; Steriade, Jones, and Llinas, 1990). The only known interactions between channels within the thalamus occurs by means of the lateral inhibitory links between cells of the reticular nucleus. Therefore, it would seem that the separate channels of impulses from thalamic inputs to thalamic outputs follow a precise local coding scheme (Jones, 1985).

Furthermore, the lateral inhibitory computations of the reticular nucleus cells could be expected to sharpen local gradients of neural activity across the cortical columns (in somewhat the same way that horizontal cells enhance contrast in the retina), so that impulses that are routed through the thalamus may serve to concentrate neural activity spatially rather than to spread it. This principle may hold generally for a cluster of input fibers carrying a vector-coded representation, even considering that a typical thalamocortical axon spreads across a 2.0–2.5-mm diameter area within cortex (Kaske, Dick, and Creutzfeldt, 1991) and that thalamocortical axons terminating in primary visual, auditory, and somatosensory areas may be restricted to a 1–2-mm area (Ferster and Levay, 1978; Gilbert and Wiesel, 1983). In contrast to the isolation of thalamic columns (except for the local lateral inhibitory connections in the reticular nucleus), the columnar organization in the cortex is characterized by extensive interconnections between neighboring columns (for a relevant review, see Toyama, 1988; Felleman and Van Essen, 1991), which enable activity in one column to enhance as well as suppress activity in neighboring columns.

The remaining part of the circuit diagram of figure 49.4 concerns the reticular nucleus cells and the interneurons, both of which are inhibitory (Jones, 1985); the reticular nucleus cells provide recurrent inhibition, and the interneurons provide feedforward inhibition. In the case of the reticular nucleus cells, the main axon fiber enters the main body of the thalamus, spreads its terminals widely (Yen et al., 1985), and forms synapses not only with relay cells but also with interneurons (Montero and Singer, 1985). This pattern of connectivity enables reticular nucleus cells to reduce the inhibitory influence of interneurons at the thalamic afferent input (Steriade, Domich, and Oakson, 1986).

Often overlooked in circuit diagrams of cortical and subcortical areas is the ubiquitous presence of axon terminals arising from nuclei in the brain stem and basal

FIGURE 49.5 Simulated trajectories of target and distractor firing rates of cortical neurons, based on the network model of the thalamocortical circuit shown in figure 49.4. (Adapted from LaBerge, Carter, and Brown, 1992.)

forebrain (Jones, 1985; Steriade, Jones, and Llinas, 1990). Neurotransmitter substances secreted by these axon terminals modulate in a diffuse manner both the synaptic connections between thalamic cells and the intrinsic membrane properties of cells that affect spontaneous firing and thereby influence states of sleep and arousal (McCormick, 1992).

Given the relatively well-known anatomical structure of the thalamic circuit, it is possible to determine by simulation methods whether the output of the thalamocortical circuit is suitable for producing the selective expression of attention in cortical columns. The results of one simulation study (LaBerge, Carter, and Brown, 1992) assumed that the input to the thalamocortical circuit represented sensory activations arising from a display containing a target item with adjacent distracting items on each side of it. Each item was represented by five columns of the kind shown in Figure 49.4, with two columns for the spaces between them. The simulations were carried out for each of the three variations of the thalamocortical circuit described earlier in this section. All three simulations produced the same pattern of selective trajectories for the target and distractor, which is the pattern shown in figure 49.1D.

An example of a more recent simulation of the thalamocortical network operation is shown in figure 49.5. The only modification of the network parameters of the first simulations was that the input from corticothalamic axons at the distal dendrites of the relay cell lowers the threshold of the cell instead of inducing it to fire (McCormick and Von Krosigk, 1992); thus there is an increase in the synaptic weight for the afferent input to the relay, with the consequence that the effect of incoming spikes from afferent axons synapsing near the

FIGURE 49.6 Trajectories of neural firing for the good (target) stimulus and the poor (distractor) stimulus. The animal produced a saccade to the target at time 0 (Chelazzi et al., 1993).

relay cell body are potentiated. The resulting selection trajectories were similar to those of the original simulation study, conforming to the expression pattern shown in figure 49.1D. The simulated trajectories of V4 cell activity, shown in figure 49.5, may be compared with the measurements of single-cell activity, shown in figure 49.6, of a monkey engaged in a selective attention task. The simulated trajectories of attentional selection show that small differences in firing rates between target and distractor top-down inputs can be magnified by a factor of at least 25 by the characteristics of the thalamocortical network.

The set of equations on which the simulation of the thalamocortical network is based contains 30 parameters, a fact which imposes severe difficulties on estimating parameters from empirical tests of the network. A different formulation of the thalamocortical network is based on equations containing only 11 parameters, of which 7 are fixed and 4 are free to vary (LaBerge, Carlson, and Williams, 1997); these equations can be solved by analytic methods, in contrast to the numerical method of simulation. This analytic model of the thalamocortical circuit produces pairs of trajectories that closely match the pattern of the pairs of trajectories generated by the network model (figure 49.5).

In evaluating the results of the present simulations, it should be noted that the finding that the thalamic network can greatly magnify a target-surround input difference by a large enhancement component with a relatively small suppression component does not prove that the thalamic network in fact operates in this manner. Rather, the simulation result has the status of an ex-

istence proof, which states that the thalamic circuit could instantiate a magnification of the target-surround contrast in the manner shown by Figure 49.1D. However, taken together with the PET evidence for thalamic activation (and some, e.g., Maunsell, 1995, but not all single-cell evidence, e.g., Moran and Desimone, 1985), the simulation of the thalamocortical network's operation supports the hypothesis that the thalamocortical circuit amplifies activity in cortical columns corresponding to the target of attention (relative to the activity in the surrounding columns) and thereby serves as a mechanism of the expression of attention.

The control of attention

The mechanism that produces the expression of attention in cortical columns, whether it be a thalamocortical circuit or a circuit intrinsic to a cluster of cortical columns, is unlikely to initiate the pattern of attentional activity by itself. Rather, the initiation of attentional activity in these mechanisms is presumed to be controlled by sources outside itself—for example, by afferent inputs from other cortical columns or by inputs from the superior colliculus (figure 49.4, bottom). The sources of control are commonly believed to be of two major types: bottom-up (exogenous, stimulus-driven) control and top-down (endogenous, goal-directed) control (for a review see Egeth and Yantis, 1997).

Much of the literature on attentional control is concerned with how the shifts of attention are controlled—in particular, how the shifts are triggered and how the shift process itself operates (i.e., what happens between the origin site of the shift and the destination site). Attentional control also operates after attention has shifted, to determine which of the alternative items in a display will be selected for the expression of attention and to determine the intensity and duration (dwell time) at the new locus of attention. What attention “does” for the organism (e.g., simple selection, preparation, and maintenance of neural activities) is a basic issue of this chapter, and the effects produced by the attention depend upon what happens during the time attention is being expressed, which takes place after the shift has been completed. Therefore, in this section of the chapter there will be more emphasis on the control of the expression of attention, rather than on the control of the shifting of attention.

BOTTOM-UP CONTROL OF ATTENTION Bottom-up control of attention operates in two main ways: triggering shifts of attention (often termed attentional capture) and guiding attention to particular locations in the visual field. Examples of a stimulus that initiates a shift of at-

tention are a bar marker flashed near the location of an impending target object (Eriksen and Hoffman, 1972; Jonides, 1981) or the abrupt increase in luminance of a square located to the right or left of a central fixation point (e.g., Posner, 1980). It was proposed by Yantis and Jonides (1984) that these kinds of stimulus changes trigger shifts of attention because they share the property of an abrupt character of the stimulus onset.

Recently, Yantis (1996) proposed three categories of attentional capture: *strongly involuntary*, when a stimulus event captures attention when the subject is actively ignoring it; *weakly involuntary*, when an irrelevant stimulus event captures attention while the subject is not actively ignoring it; and when a subject actively searches for a particular *feature singleton*. Thus, whether or not a bottom-up sensory event will trigger an attention shift depends upon the momentary top-down control. A similar view of attentional capture is given in the guided search model of Wolfe (1994), in which attentional priorities in search are dependent jointly on bottom-up and top-down influences.

The display conditions that are less obligatory with respect to attentional shifts are feature singletons, which could be said to guide rather than trigger attentional shifts. Feature singletons have been described in the literature as items that appear to “pop out” during the search of an array of objects, by virtue of possessing a unique (and salient) feature, relative to the other items of the search array (Treisman and Gelade, 1980; Treisman and Gormican, 1988). The process by which an object defined by a unique feature is detected in these search tasks is described as a preattentive process, in contrast to the attentive process that is directed successively to item locations when the object is defined by a conjunction of features. Thus the feature singleton in an array of items first is detected, and then it guides the shift of attention to its location. According to Treisman's theory (Treisman, 1998), the simple features that constitute items in a search display are initially registered in parallel within separate feature maps, which are connected to a master map of location. Shifts of attention to location are carried out in the master map, and presumably only one shift is necessary when the target is defined by a feature singleton, whereas a succession of shifts to various item locations is required when the target is defined by a conjunction of features.

Thus, when an array of items is displayed (e.g., in a search task), the location map may be pictured as containing a set of activity peaks, each representing the initial registration of an item's location, with the activation of a feature singleton's location being higher than that of its neighboring items. This initial registration of object locations is preattentive, and has been described as

“spatial indexing” in a model by Wright and Ward (1998). Preattentive registration of an object’s location has also been described in terms of an “activity distribution” within a location module of the brain (LaBerge and Brown, 1989; LaBerge et al., 1997).

TOP-DOWN CONTROL OF ATTENTION A changing sensory environment typically presents the system with an ongoing array of abrupt stimulus onsets and locally defined stimulus contrasts that operate as feature singletons. In order to respond effectively to this environmental flux, the system expresses attention to only a small part of this stimulus input. When a display of many objects is presented, the locations of those objects are presumed to be indexed spatially by individual peaks of activity distributions in a brain map, which is presumed to be located in parietal areas. The pattern of locations of these activity distributions is then projected to prefrontal areas that control attention to spatial locations, in particular the dorsolateral prefrontal area. A core premise of this chapter is that further processing in this and related frontal areas then determines which of these parietal activity distributions will be converted into an expression of attention by projecting to it, in the top-down direction, additional activation that is sustained for some minimal time.

Sites of top-down attentional control are presumed to underlie systems of working memory, in which (following the theory of Baddeley, 1995) two kinds of processes dominate: storage of information in a highly accessible form over a short period of time; and executive control, which governs encoding, retrieval, and commands for the expression of attention.

In the monkey prefrontal cortex, neurons that are active during the delays between a sample display and a test display appear to be clustered in anatomically distinct regions according to whether they are selectively responsive to spatial locations and the shape and color of objects (Wilson, O’Scalaidhe, and Goldman-Rakic, 1993), and to the identity of faces (O’Scalaidhe, Wilson, and Goldman-Rakic, 1997). Using PET measures with humans, Smith and Jonides (1997) indicated different working-memory systems for spatial, object, and verbal information.

The sustaining of information over a delay period would seem to be required in order to generate preparatory attention to an appropriate object or location prior to the appearance of a target. But keeping information in a state of high accessibility over a period of time does not imply that it is also generating an expression of preparatory attention: stated otherwise, the expectation for an upcoming event is not necessarily accompanied by an attentional preparation for the event (LaBerge,

1995b). The what, where, and when of an upcoming display of an object may be held in working memory involuntarily while simple selective attention may be directed elsewhere (Miller, Erickson, and Desimone, 1996), but attentional preparation to perceive that object is a voluntary act and interferes with attending elsewhere at the same time. This separation of expectancy and preparation in the attentional control process is consistent with the separate processes of information maintenance and executive control in theories of working memory.

The amount of attentional control (for simple selection as well as for preparation) and the amount of working memory load may vary somewhat independently in tasks, so that it would be expected that the neural circuitry underlying these components would be located in different sites of the frontal cortex. Owing to its action property, the command component of attentional control would seem to lie nearer the premotor areas than the memory component of control, but the two sets of circuits may be too close to show separated sites of activation in many PET and fMRI studies. However, attention-related activations have been shown in premotor areas in several PET studies (Corbetta et al., 1993; Haxby et al., 1994; Liotti, Fox, and LaBerge, 1994; Nobre et al., 1997). Additional research is needed to design tasks that allow a clearer separation of the frontal sites that underlie components of attentional control.

The triangular-circuit theory of attention

Under the first three major headings of this chapter are treatments of issues and evidence related to three different aspects of attention and the brain sites in which they are presumed to be located. At any moment while attention is being expressed, all three sites are presumed to be active by virtue of their interconnections. It has been proposed that the pattern by which these three sites are connected is a triangular circuit (LaBerge, 1995a, 1995b, 1997a, 1998).

Control areas of the prefrontal cortex send fibers to cortical columns where attention is expressed in the monkey inferotemporal area (Webster et al., 1994) and in the parietal area (Goldman-Rakic, Chafee, and Friedman, 1993), but another pathway of fibers also connects these prefrontal areas with these posterior cortical columns. The fibers in the other pathway connect with cells within the pulvinar, and cells in the pulvinar connect with the posterior cortical columns (Asanuma, Andersen, and Cowan, 1985; Romanski et al., 1997). Therefore, the two pathways that connect a prefrontal area of control with a cortical area of expression appear to form a triangular circuit.

FIGURE 49.7 Schematic diagram of the triangular circuit connecting neurons of a V1 column with neurons of a V2 column. Direct connections arise from Layer 2 of V1 and terminate in middle layers of V2; indirect connections arise from Layer 5 of V1, synapse on a thalamic relay cell, and terminate in middle layers of V2. For simplicity of illustration, reticular nucleus neurons are not shown here.

The present theory assumes that the direct link within the triangular circuit functions primarily to select which columns of attentional expression shall be activated, and the indirect link through a thalamic nucleus functions to intensify activity in the selected columns. These two functions of selection and intensification, represented by each pathway within the triangular circuit, can be viewed as informational and modulatory aspects of attentional control, respectively. In order to clarify the way in which the triangular circuit separates the informational and modulatory aspects of signaling between cortical areas of attentional control and expression, we present a description of the general structure of the triangular circuit inferred from neurotracing studies. Most of the knowledge we have of cortical and thalamic circuitry has been obtained from studies of area V1 and its adjacent cortical areas, for example, V2. It is known that fibers from V1 cells synapse in the pulvinar nucleus of the thalamus (e.g., Ungerleider, Galkin, and Mishkin, 1983) and that these fibers arise from large pyramidal cells in Layer 5 and from smaller pyramidal cells in lower Layer 6 (Conley and Raczkowski, 1990). Relay neurons in the pulvinar project directly to neurons in area V2 (Jones, 1985), as well as to other visual areas in the posterior cortex (including area V1).

Figure 49.7 shows a schematic diagram of the direct (forward) fiber arising from Layer 2 of a V1 column and terminating in the middle layers of a V2 column. An indirect fiber connecting a V1 column with a V2 column arises from Layer 5 of a V1 column and terminates on a

relay cell in the pulvinar, which in turn projects to the middle layers of a V2 column. (The indirect fibers that arise from lower Layer 6 are not shown here.)

The indirect connection between V1 and V2 that involves thalamic neurons appears to have properties that can enhance firing rates in V2 columns. Neurons in Layer 5 fire in bursts of a few spikes at rates at least as high as 250 Hz, with intraburst firing rates of approximately 15 Hz (Connors and Gutnick, 1990; Gray and McCormick, 1996); therefore, these neurons have the ability to drive their target neurons to high rates of firing. Axons of these intrinsically burst-firing cells synapse near the cell bodies of thalamic relay neurons, and this dendritic location provides a privileged position from which to drive the spike outputs of the relay neuron. The neurons arising from upper Layer 6, whose axon fibers have smaller diameters (and thus can be distinguished from those of Layer 5), synapse mostly at remote locations on the dendrite (Sherman and Koch, 1990). These (upper) Layer 6 neurons appear to function by lowering the threshold of the thalamic neuron to signals arriving at synapses near the cell body (McCormick and Von Krosigk, 1992). Therefore, the corticothalamic feedback loop involving Layer 6 neurons facilitates the synaptic efficacy of Layer 5 axons, and thereby potentiates the already strong effects of the bursting Layer 5 neurons on the relay neuron. These properties were incorporated into the network simulation of the thalamocortical circuit described earlier in this chapter, whose output trajectories are shown in figure 49.5.

Triangular circuits are assumed to exist within and between other cortical areas. Large Layer 5 fibers synapse near the relay cell body, and small Layer 6 fibers synapse at the distal locations on the relay cell dendrites for the auditory cortex (Ojima, 1994) and the prefrontal cortex (Schwartz, Dekker, and Goldman-Rakic, 1991). Because all regions of the cortex are connected with a nucleus of the thalamus, it seems highly probable that the triangular circuit exists wherever cortical columns in one area communicate with columns in another area. Samples of triangular circuits that are particularly relevant to attentional processing in the brain are shown in figure 49.8 (LaBerge, 1995a, 1995b). These proposed triangular circuits function to amplify corticocortical connections in both bottom-up and top-down directions, and it is conjectured that the enhancement operations provided by the thalamic part of the triangular circuit typically are stronger and of longer duration when the circuit involves top-down sources of activation than when it involves only bottom-up sources of activation (e.g., from abrupt onsets and feature singletons).

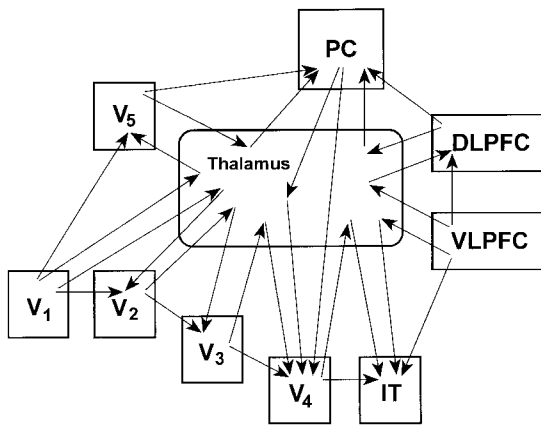

FIGURE 49.8 Some samples of the triangular circuits that are presumed to be involved in visual attention. The top-down triangular circuits serving visual attention are assumed to involve working memory circuits in the dorsolateral prefrontal cortex (DLPFC) for location and in the ventrolateral prefrontal cortex (VLPFC) for shape.

Direct connections from prefrontal areas of control to posterior areas are assumed to carry the signals that select the columns of attentional expression of perceptual events; therefore, this link in the triangular circuit is considered informational. One may question whether or not these fibers also carry the range of firing rates needed to induce varying degrees of intensity in the target columns; high rates of intensity can obscure the temporal properties of a signal train that is precisely tuned to choose the appropriate columns for attentional expression. Modulatory signaling of attentional control can be separated from the direct route serving informational signaling by means of the indirect route from prefrontal areas through the thalamus.

A triangular circuit of attention connecting the frontal, pulvinar, and parietal areas is illustrated schematically in figure 49.9. The frontal area (which may include premotor and prefrontal areas) is presumed to serve the storage and executive components of control (for a review of studies showing interconnections of parietal, prefrontal, and premotor areas see Selemon and Goldman-Rakic, 1988). In this example, a site in frontal cortex selects the site of attentional expression in columns of the parietal cortex and regulates the intensity of the cortical expression in these columns by means of the indirect connection through a thalamic nucleus. Since, in general, the posterior cortical areas code for perceptions and the anterior cortical areas code for actions, sites of attentional expression for actions are assumed to exist in the frontal area.

A metaphor for the operation of the triangular circuit of attention is the operation of a compact disc player (CD player). The CD player is assumed to contain a

bank of thousands of discs (corresponding to column clusters in the cerebral cortex, which code memories of possible cognitive events). Selection of a disc occurs from the controlling hand (prefrontal/premotor cortex), which also adjusts the gain (thalamocortical circuit) of the disc. Discs may be initially activated bottom-up (from a fixed connection with the internet), but the disc is not heard unless the controlling hand turns up the gain for some minimum duration of time (LaBerge, 1997a, 1998).

CONTROL OF THE PREFRONTAL EXECUTIVE CONTROL The issue of the executive control of attention leads to the question of how the controlling operations of the frontal sites are themselves controlled. The thalamocortical loops in the frontal cortical areas (and not in the posterior cortical areas) are tonically inhibited by fibers from the basal ganglia (Alexander and Crutcher, 1990), specifically, from the substantia nigra (pars reticulata) and the globus pallidus (Ueki, 1983; Uno and Yoshida, 1975). The basal ganglia are directly connected with limbic areas and therefore provide a route by which motivational activities of the brain can influence action-related activities of the frontal cortex. Activity in the basal ganglia—for example, during working memory tasks (Levy et al., 1997) and concentrated preparatory attention tasks (Liotti, Fox, and LaBerge, 1994)—presumably results in the inhibition of inhibitory output fibers of the basal ganglia, so that the thalamic relay neurons receiving these fibers are released from the tonic inhibition of the basal ganglia and are free to activate columns of neurons in the frontal cortex within the thalamocortical loop (see figure 49.10). A more thorough discussion of the present view of basal ganglia control of frontal cortical columns is presented elsewhere (LaBerge, 1998), along with a diagram of the basal ganglia circuitry that connects with the triangular circuit of attention.

OPERATION OF THE TRIANGULAR CIRCUIT When the triangular circuit produces the expression of attention, it is presumed to be active over some minimum of time, and during this time interval activity flows repeatedly in both directions between the frontal control site and site of expression (figure 49.10). It is assumed that sustaining top-down activity directed to a site of attentional expression requires quasi-coincident detection of the top-down command and the resulting feedback from the site of expression. In somewhat the same manner, speaking aloud requires continuous feedback from hearing what is spoken, and when the time interval between the feedforward and feedback events is large, the act of speaking cannot be effectively sustained. Maintaining the appro-

FIGURE 49.9 A schematic example of a triangular circuit of attention, with the expression of attention in the parietal area, the control of attention in the frontal area (prefrontal and/or premotor area), and the amplification of attentional activity in the thalamic nucleus (pulvinar) serving the parietal area. An

abrupt stimulus onset is assumed to initiate brief parietal activity, regarded as an expression of orienting; prolonged parietal activity subsequently sustained (or initiated and sustained) by the top-down triangular circuit is regarded as an expression of attention.

appropriate timing between feedforward and feedback events within the triangular circuit of attention depends upon precise timing in frontal circuit activity, which is apparently affected strongly by the neurotransmitter fibers that pervade the frontal areas (e.g., Goldman-Rakic et al., 1992).

Attentional duration corresponds to the duration of cycling through the reciprocal triangular circuit of figure 49.10. Durations may be brief, as in the short dwell times during visual search, or long during preparatory attention for an upcoming target. A search display preattentively indexes locations of items by establishing small peaked activity distributions for each (regarded here as expressions of orienting), and then top-down attentional control selects one location after another by adding activity to the existing peak by means of a triangular circuit (see figure 49.9). The duration of top-down activity is presumed to be short for each location until a match is found, and then the triangular circuit sustains activity for a moderate duration. Similarly, when an abrupt onset of a luminance change indexes a location preattentively in the parietal location map and then in the frontal control map, attention is not considered to be expressed until the frontal map returns at least a moderate duration and intensity of activity through the triangular circuit to the parietal map.

FIGURE 49.10 Schematic diagram of reciprocal triangular circuits connecting a site of attentional control with a site of attentional expression. Shading within rectangles represents levels of activity within a cortical column (dark is high, white is near-zero activity). Thalamic nuclei serving frontal cortical columns are tonically inhibited by fibers arising in the basal ganglia (BG); here the BG axon is shown to be disinhibited (by fibers from other brain areas), so that thalamic cells can increase activity in a frontal cortical column.

The circuit shown in figure 49.10 suggests two factors that contribute to the one-at-a-time property of attentional expressions. One factor is indicated by the activity contrast between a target column and neighboring columns, represented in figure 49.10 by the shading in the

target column and the absence of shading in its neighboring column. At least some of the circuits responsible for the difference in column activations are the lateral inhibitory connections in the thalamic reticular nucleus (figure 49.4), which increase their inhibitory influence on neighboring columns as the activity in the target column increases. A second factor is the projection to the thalamic relay cell from the basal ganglia, which is selectively disinhibited in this example, while other thalamocortical loops serving other frontal columns are being tonically inhibited.

When reciprocal activity in a triangular circuit is intense, the resulting increased inhibition of neighboring columns of control provides protection from interruption by abrupt onsets of unattended stimuli, which normally activate these neighboring columns. This protective property is assumed to be mainly responsible for the longer detection times of uncued versus cued locations in visuospatial tasks. Thus the time to respond to an uncued probe stimulus can be used as a measure of the intensity of attention directed to the cued task (e.g., LaBerge, 1973).

Conclusions

A basic premise of this chapter is that the expression of attention in its manifestations of simple selection, preparation, and maintenance is produced by the intensification of neural activity in particular clusters of cortical columns. The expression of attention requires simultaneous activity in two other brain regions: the frontal areas, which control the selection and amplification commands; and the thalamus, which contains the amplification circuit mechanism. These brain sites of expression, mechanism, and control are assumed to be interconnected by a triangular circuit, and when simultaneous activity in the three sites is sufficiently prolonged and intense, it is conjectured that an attention state exists.

Introduction

ENDEL TULVING

Memory is the capacity of nervous systems to benefit from experience. It is a ubiquitous presence in all higher life forms. It takes many shapes, from simple to complex, from highly specific to most general, from trifling to fundamentally important. In its manifold expressions it is being observed, investigated, and measured in numerous organisms, at many different levels of analysis, from a variety of vantage points, and relying on many different approaches and techniques. It reaches its evolutionary culmination in human beings.

The study of memory has occupied the center stage of cognitive neuroscience since its inception. It continues to fascinate and frustrate large numbers of capable scientists. Novel findings are reported almost daily, yet the major insight gained from more than one hundred years of scientific study of memory may be the realization that the complexity of memory far exceeds anyone's imagination. It is clear that memory did not evolve for the convenience of the neuroscientist.

The nine chapters in the memory section of the second edition of *The Cognitive Neurosciences* provide summaries of and glimpses into some of the more active foci of contemporary cognitive neuroscience of memory. Six chapters deal solely or primarily with human memory, whereas three others focus on work done with nonhuman primates. Collectively, they illustrate the variety of methods and procedures used. These include electrical recording from single neurons in monkeys (chapters 50 and 51) and from multiple scalp sites in normal human subjects (chapter 56); the study of the effects of experimentally created lesions in monkeys (chapter 52) and the mnemonic consequences of brain damage resulting from disease or accident (chapters 53, 54, and 58); effects of psychoactive drugs (chapter 55); and functional

neuroimaging of memory-related processes in healthy volunteers (chapters 57 and 58). The overarching concern in all these chapters is to gain insight into the neuronal substrates of behavioral and cognitive manifestations of learning and memory and into the nature of the relation between neural mechanisms and memory processes.

Because of the vast size and diversity of the domain, it simply is not possible to deal with memory as a whole. Nor is it possible to make any intelligent generalizations about it. Any claim about “memory” or “memory impairment” immediately requires clarification: About which kind of memory, memory task, memory process, or memory system are we talking? These terms define the major fault lines along which the whole of memory can be fractionated into more manageable components within which generalizability of factual statements and theoretical claims are more likely to be valid. The concepts represented by these terms have evolved from the observations made about memory at the level of observable behavior and reportable experience. Directly or indirectly, they provide the backdrop against which we seek to understand the relation between brain and behavior or between brain and mind.

This introduction to the section on memory describes the outlines of the conceptual framework within which much research on human memory is conducted and attempts to clarify some of the arcane terms that, although useful to insiders, frequently mystify outsiders. It touches on topics such as memory systems, memory tasks, memory processes, and conscious awareness in memory.

Memory systems

The concept of memory systems is one answer to the need to specify different “kinds” of memory. Different systems share certain basic features, such as some device or means of retaining the consequences of a current act of behavior or cognition, and they differ with respect to others, such as the functions they serve, their behavioral or cognitive manifestations, the principles of their operations, and the brain mechanisms involved in the operations.

The most fundamental division in memory deals with the distinction between behavior and thought. Many forms of learning and memory are expressed in behavior (doing something, carrying out a procedure), whereas others are expressed in thought (contemplating something, being cognizant of some mental contents). The behavioral kinds collectively are referred to as “procedural” memory; the ones expressed in thought are referred to as “cognitive” memory. Although the distinction is not a simple one, a rule of thumb that can be used for deciding how to classify any particular act

of memory consists in the answer to the question—can one hold in mind the *product* of the act of memory? An affirmative answer suggests that memory is cognitive; the negative answer means that it is procedural.

The distinction between procedural and cognitive holds very broadly for learning and memory in many species. Other terms have been used to designate them. Procedural memory has been called habit memory, non-declarative memory, and even implicit memory, although for many students of memory, implicit memory means something rather different than the broad category of learning and memory that is not cognitive. Cognitive memory has been called declarative memory, propositional memory, and also explicit memory, although, again, explicit memory does not really correspond to all forms of learning and memory that are not cognitive. The extensive, and sometimes undisciplined, use of different terms to designate the same underlying concepts is a continuing problem in the field.

Cognitive memory, which constitutes the lion’s share of memory research with human subjects, can be further subdivided into four major categories, or “systems.” They are (1) working memory, whose function is to hold information “on line” over short intervals of time while cognitive operations are performed on it; (2) the perceptual representation system, whose function is to mediate memory-based facilitation of perceptual identification of objects; (3) semantic memory, whose function is to mediate the acquisition and use of individuals’ general knowledge of the world; and (4) episodic memory, whose function is to mediate conscious access to the personally experienced past.

The separability of the four systems from one another is widely if not universally accepted. The distinctions among them receive support from sharp dissociation between task performances that depend heavily on the different underlying systems in normal subjects and brain-damaged individuals, as well as from functional neuroimaging and psychopharmacological studies. Relevant evidence is discussed in many chapters in this section. Much of the research effort currently is directed at the refinement and elaboration of the taxonomic scheme, and at the identification and characterization of the many subdivisions of the major categories.

Tasks and processes

Cognitive memory in the laboratory is studied in segments of reality called *tasks*. A typical cognitive memory task consists of three stages: (1) presentation of some material to the subject, usually with instructions to “remember” it; (2) a retention interval during which the subject may engage in other (mental) activities; and (3) a test of

the subject's knowledge of the originally presented material. The outcome of the test is expressed in terms of some measure of the subject's performance on the test. It is frequently but not necessarily a measure of how well the subject can reproduce originally presented material.

A great variety of cognitive memory tasks exists, defined in terms of a large number of possible variations in the specific features of the three stages of the task. Tasks can vary in the kinds and units of the material presented for learning and the specific parameters of the presentation, the length of the retention interval (which can range from seconds to years), the nature of the "interpolated" activities, and many other independent variables. An especially important feature of the task is the nature of the test. Tests also can vary widely with respect to the instructions that specify the subject's mission and the nature and type of cue information provided to guide and aid its execution.

Given this thumbnail sketch of the memory task, how are we to think about and describe, in general abstract terms, what happens when the subject is engaged in a cognitive memory task? For a long time in the history of learning and memory the dominant theoretical concept that provided the answer to this question was "association." During learning, associations were assumed to be formed, maintained in force, sometimes interfered with, and then expressed in behavior. The concept of association still is used in special situations, especially in studies of learning and memory with nonverbal subjects. In the mainstream cognitive psychology, however, some 30 to 40 years ago the associative paradigm was replaced by *information processing* as the general pretheoretical framework. This framework currently determines how most students of memory think and talk about the workings of memory.

The three sequential stages of the standard memory task correspond to three major memory processes of encoding, storage, and retrieval. The presentation of the to-be-remembered material is an event about which "information" is "encoded" into the memory "store." Usually, the material consists of discrete items (words, pictures, objects, faces, and simple sentences), and the presentation of each is a "miniature event" about which information is encoded into the store. During the retention interval, this information is maintained in the store as an "engram," and it may be "consolidated" or "re-coded." *Consolidation* is thought of as a biologically determined autonomous process that runs its course independently of the interpolated activity, whereas *re-coding* is an active psychological process that is shaped by the particulars of the interpolated activity. At the time of the test, the information "available" in the engram is "retrieved," or rendered "accessible." *Retrieval* means

use of stored information, and because stored information can be used in many different ways, the term retrieval is very broad and usually needs to be specified more precisely.

The concept of information runs through this pretheoretical processing framework like a red thread. It is useful to keep in mind, therefore, that neither *information* nor *process* can be defined readily. Information simply is the intangible, ineffable, unknown "stuff" that is somehow created, transferred, transformed, preserved ("processed") in the mind/brain, which, when appropriately "converted," determines behavior and conscious thought. Both information and process are "placeholder" concepts in contemporary cognitive sciences. They will be used until a better paradigm comes along. Even though they are not readily definable, the terms make abstract thought about the workings of the brain/mind possible and the doubts about how to best study it tolerable.

Conscious awareness in memory

The products of retrieval in all cognitive memory tasks are, in the first instance, expressed as mental experiences. They can be contemplated internally, in the absence of any overt behavior, and they can be "held in mind." It would be normal to expect, therefore, that the efforts to understand cognitive memory be directed at the study of the retrieval experience. For a long time in the history of the science of memory, however, this was not done. Subjects' memory performance invariably was measured in terms of behavioral indices of various kinds. The tacit assumption, seldom explicitly formulated, was that behavioral output in the memory test faithfully reflects the mental contents of what the individual has retrieved from memory. We now know that this assumption does not always hold.

Recently, the issue of individuals' conscious experiences that accompany the act of retrieval from the memory store has been shifted into a sharp focus, in two different ways. One distinguishes between "conscious" and "nonconscious" retrieval; the other, concerned solely with conscious retrieval, distinguishes between two forms of it. The first issue is dealt with under the heading of *explicit versus implicit* memory, the second under the heading of *remembering and knowing*, or *recollection and familiarity*. We consider them in turn.

Explicit and implicit memory

The first issue of consciousness in memory has to do with the rememberer's awareness, at the time of the test, of the relation between the current experience (and activity)

on the one hand, and the original learning or encoding episode on the other. In ordinary everyday-type of remembering, the relation is clearly felt: when the individual recollects a previous event, such as the study of some specific material in the first stage of the experiment, he or she also is fully aware that what he or she is experiencing has its origin in the earlier episode. The technical term that is used currently to refer to this kind of awareness at retrieval is *explicit* memory.

Explicit memory contrasts with *implicit* memory: retrieval of stored information in the *absence* of the awareness that the current behavior and experience have been influenced by a particular earlier happening. It is in this sense, and this sense only, that explicit memory is said to be “conscious,” whereas implicit memory is “nonconscious.” Consciousness refers to the awareness of the *relation between* the present thought (and action) and a *specific* previous thought (or action).

An important point to note is that the distinction between explicit and implicit memory is that between explicit and implicit *retrieval*—that is, the distinction applies only the final stage of our typical memory task. This is because there is no difference between explicit and implicit encoding, and there is, as yet, no known way to distinguish between explicit and implicit storage. For this reason among others, explicit and implicit memories do not qualify as memory “systems.”

In memory experiments, explicit retrieval is effected by the instructions given to the subject at test: “Remember what you saw, or what you did, or what happened to you at some earlier time, in some place (such as the first stage of the experiment)?” Implicit retrieval, too, is experimentally effected by the instructions given to the subjects at the time of retrieval as to what they are to do. Many different forms of implicit memory tests exist and have been used, but they all have in common the fact that the subject *need not* think back to the first stage of the task, or to any other specific episode, to perform the task at a level that has benefited from the first stage. Thus, implicit memory satisfies the definition of memory—the individual benefits from experience, but he or she is unaware that he or she has done so.

It is important to note a complication: Explicit retrieval instructions do not necessarily guarantee that the responses made by the subject are accompanied by a sense of recollection, as they ideally would. Subjects’ explicit memory performance may be influenced by processes that support implicit retrieval. Nor do implicit instructions guarantee that retrieval occurs in the absence of recollection of the relevant encoding experience, as it ideally should. Purification of research designs aimed at reducing or eliminating such unwanted “contamination” of the desired type of retrieval by extrane-

ous factors is an important part of research on explicit and implicit memory. Some of these issues are discussed in chapters 55, 56, and especially 58.

Many experiments, of many different kinds, have convincingly demonstrated the reality of the distinction between explicit and implicit memory. The major theoretical import of the discovery of these two forms of retrieval lies in the sharp distinction that they draw between overt behavior and the mental experience that accompanies such behavior. The subject’s ability to produce a particular over-response, whose likelihood has been enhanced by a particular earlier event, may be identical in two tests. However, the mental experiences may be altogether different.

Remembering and knowing

The second issue of consciousness emerges in situations in which the awareness of the relation between the present experience and an earlier specific event is in fact present. It has to do with two different *kinds of awareness* that may accompany explicit memory retrieval. One is referred to as *remembering* or *recollection*, the other as *knowing* or *familiarity*. In explicit tests of recognition and recall, the subject may make a correct response not because he or she actually remembers or recollects the event of the item’s earlier presentation, but rather because the recognition test item “looks familiar,” or because he or she “simply knows” that the word he or she has just recalled was in the presented list. Because the subject is fully aware of the previous presentation episode of the material, he or she—usually correctly—attributes the feeling of familiarity or “knowing” to the episode.

The remembering/knowing or recollection/familiarity distinctions currently are subjects of lively interest to many memory researchers. Rugg and Allan (chapter 56) discusses the electrophysiological evidence for the distinction, and Squire and Knowlton (chapter 53) deal with the issue of how remembering and knowing are related to the amnesic syndrome and whether they are both dependent on the medial temporal lobes. Schacter and Curran (chapter 58) and Curran (chapter 55) also touch on the distinction. The major theoretical point, however, is that here, finally, we have an active area of research aimed at the essence of cognition: Conscious *mental experiences* that have been changed as a result of earlier experience-induced physical changes in the brain.

Other levels and species

Concepts such as encoding and retrieval, explicit and implicit memory, or remembering and knowing make

good sense at the level of behavior and cognition of the whole individual, or the whole brain. They are less readily applicable to the study of memory-related events at the level of single neurons, in analyses of the kind described by Goldman-Rakic and associates and Erickson and colleagues in chapters 50 and 51, respectively. Although encoding and retrieval ultimately are rooted in neuronal activity, a single neuron cannot encode or retrieve anything. A neuron may “fire” differentially during the interval between the presentation of the target and the signal for the saccade in the oculomotor working-memory task used by Goldman-Rakic and colleagues, thus providing for a neat neuronal mechanism for holding information “on line” in the short-term memory “store.” But although it is possible to think of this “on-line holding” mechanism as comparable in principle to “holding” information in the long-term “store,” the parallel probably would not work. Retrieval—use of the “stored” information—has different meanings to the organism and is based on rather different operations, in the two situations. Similarly, a neuron may respond differentially to a stimulus when presented for the first time versus the second, as shown by the studies of Erickson and colleagues (chapter 51), and it is tempting to think of the difference as in some sense paralleling novelty versus familiarity detection, or even encoding and retrieval, at the level of the whole brain, but the two levels of analyses are too far apart to allow one to feel confident about such thoughts. A challenging task for neuroscience of memory is to determine to what extent such high-level phenomena as conscious recollection of the occurrence of an event depend on the differential activity of individual units, and to what extent they represent network-level happenings, or as yet unknown mechanisms, in the brain.

Similar thoughts apply to memory in nonhuman animals. A good deal of knowledge about memory, and especially about the neural basis of memory-based behavior, has been derived from work with other animals—nonhuman primates, rodents, birds, and others, all the way to insects, worms, and sea slugs. A major advantage of this work lies in the possibility of a greater range of surgical, chemical, and other material interventions in the normal brain activity.

Because memory capabilities, functions, and processes of any two species are always not only similar in some ways but also different in others, some of the methods, findings, and theoretical ideas about human memory have no direct parallels and no direct applicability to nonhuman animals. Thus, there are as yet no known means that could be used to separate implicit from explicit retrieval, or to distinguish between what animals remember and what they know, or what they

recollect and what they find merely familiar. Therefore, the important distinctions that shape thought about human memory cannot be transferred forthwith into the study of learning and memory in nonhuman animals. This simple fact also imposes certain limitations on the extent to which the findings from animal studies can be generalized to humans. When these limitations are kept in mind, however, and flat generalizations are avoided, study of memory in one species can be invaluable in providing useful information and offering inspiration to the study of memory in others. The basic structural similarity among the brains of all mammals, especially primates, cannot be gainsaid, and this structural similarity clearly implies *some* functional similarity as well. The challenging task is to identify exactly wherein the similarities lie.

Conclusion

This, then, is a brief description of the framework within which much of the neurocognitive research takes place. In one way or another, more or less directly, many empirical findings and most major theoretical ideas and debates involve memory processes, retrieval-related awareness, and memory systems. Study of amnesia and other forms of memory impairments, and theoretical disputes about it, revolve around issues of memory processes, memory awareness, and memory systems. Studies of functional neuroanatomy of memory, made possible by novel techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) are focused on memory processes, their interactions with the type of remembered material, and on differences between implicit and explicit retrieval.

The outsider who is not familiar with the field should gain some idea from this section about where cognitive neuroscience of memory stands at the turn of the millennium. The insider who knows what the situation was like only 5 years ago, when the first edition of *The Cognitive Neurosciences* appeared, should find that great changes have occurred since then. New techniques, such as the use of excitotoxic lesions, described by Murray (chapter 52), have produced data that, by past standards, can be regarded as revolutionary. New phenomena, such as “false remembering” discussed and dissected by Schacter and Curran (chapter 58), were not only unknown but also even largely unimaginable 5 years ago. Moreover, most everything that functional neuroimaging techniques (PET and fMRI) have revealed about human memory, as described and analyzed by Buckner (chapter 57), has been discovered in the last 5 years. Stress-related memory impairments and the real possibility that what were thought of as “psychogenic amnesias” have as real a

physiological basis as “organic amnesias,” discussed by Markowitsch (chapter 54), are newcomers on the memory scene. Even approaches that have been in use for a while, such as psychopharmacology (chapter 55), event-related potentials (chapter 56), single-unit recording (chapter 51), and the study of amnesic patients (chapter

53) have yielded new discoveries and fresh insights of a kind that attest genuine progress in the field.

These are exciting times in neurocognitive memory research. Happenings at the horizon point to the next 5 years being even more so.

50 Domain Specificity in Cognitive Systems

PATRICIA S. GOLDMAN-RAKIC, SÉAMAS P. Ó SCALAIÐHE, AND MATTHEW V. CHAFEE

ABSTRACT The majority of organisms adapt to their environment largely through a process of natural selection of genetic variation. Humans, in addition, have evolved an extraordinary capacity to behave flexibly with respect to future consequences, in tandem with expansion of the prefrontal cortex. How do the new prefrontal regions relate to phylogenetically older sensory and motor areas? Are cognitive functions organized according to a different set of principles than those that govern sensory and motor areas? To address these questions, the authors examined how a cognitive process—working memory—is organized. Their research shows that the prefrontal cortex is organized into domain-specific regions based on anatomical connections with high-order sensory association areas. In addition to being consistent with anatomy, electrophysiology, and the effects of experimental lesions, the domain-specific hypothesis provides a sensible way for higher-order cognitive processes to evolve from nervous systems that respond largely on the basis of sensation and movement.

The majority of species respond to their environment in a stereotypical fashion determined by their evolutionary history and current stimulus milieu. For most organisms adaptability is a matter of selection of genetic variation within individuals, each of which responds to the environment in an unlearned and largely mindless fashion. Against this panorama of stimulus-driven organisms, there came a time in evolution when a member of the genus *Homo* became capable of verbal intelligence and unprecedented forethought. Which corresponding step was taken in the phylogenetic development of the brain? The mechanisms that enabled such an unparalleled capacity to behave adaptively with respect to future consequences coincided with the evolution of a greatly enlarged prefrontal cortex in primates in general and particularly in humans. In this chapter, we discuss recent work from our laboratory that explores, at the level of proximal causation, the functional organization of prefrontal areas involved in one of these abilities—working memory. In particular, we show that prefrontal mechanisms are constrained by content at the cellular, circuit, and areal levels determined by circuit relationships with the posterior association cortices. We begin with a review of the cellular underpinnings of these processes.

Cellular specificity of the dorsolateral prefrontal cortex: The neuron's "memory field"

The human prefrontal cortex accounts for approximately one fourth of the cerebral surface and has been mapped by a variety of methods, including single-unit recording in nonhuman primates and functional imaging in both monkeys and humans. Single-neuron recording, however, is the only method currently capable of dissecting the neuronal elements involved in the working memory processes. We have applied this method in conjunction with performance on an oculomotor-delayed response (ODR) task, in which the location of a briefly presented visuospatial stimulus is maintained in working memory to provide guidance for subsequent saccadic eye movements (figure 50.1A, upper left). An essential feature of this task is that the item to be recalled has to be updated on every trial in analogous fashion to the moment-to-moment process of human mentation. Similar tasks have become paradigmatic for probing working memory both in animals and human imaging studies (figure 50.1C–E).

Prefrontal neurons with “memory fields” are particularly relevant to our discussion of cellular mechanisms. The concept of a memory field is based on the finding that a given prefrontal neuron increases its firing rate during the delay period of the ODR task only for specific spatial locations and this preference is constant across trials. For example, the neuron shown in the upper portion of figure 50.2 is activated consistently on every occasion that the monkey must recall a particular location. Further, in instances in which the firing of a neuron is not maintained throughout the delay and the activity falters, the animal is highly likely to make an error (Funahashi, Bruce, and Goldman-Rakic, 1989). The finding that neuronal firing is location specific and directly associated with accurate recall provides a dramatic example of a compartmentalized and constrained architecture for memory processing reminiscent of that observed in sensory systems. This is an important observation because it suggests that each neuron is dedicated to a specific type of information. Furthermore, individual neurons capable of holding specific visuospatial coordinates “on line” appear to be aggregated into a circumscribed region of prefrontal cortex. Within this region are columnar units defined by common visual-

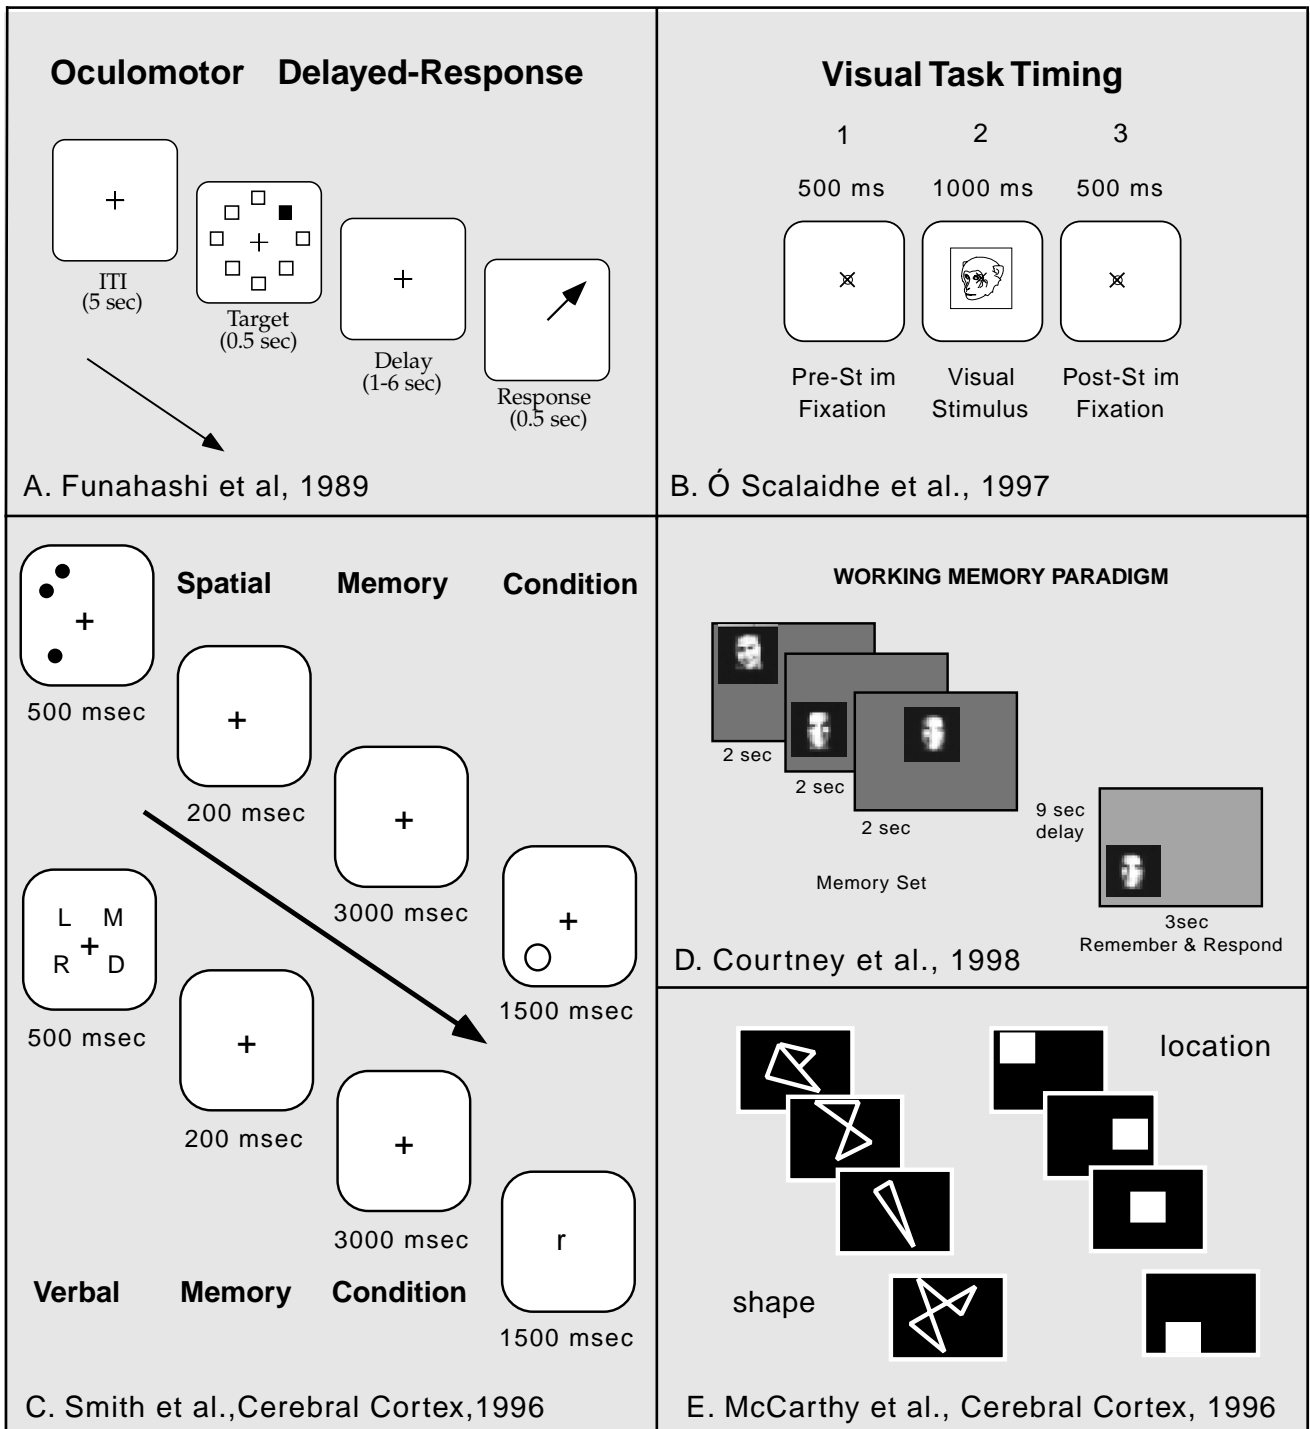

FIGURE 50.1 Common design of working memory paradigms as employed in studies of nonhuman primates (A and B) and humans (C–E). All tasks employ sequential presentation of

the item or items to be recalled (shapes, letters, words, or markers of location), delay periods between items over which items must be recalled, and recall or response epochs.

spatial coordinates (Ó Scalaidhe and Goldman-Rakic, in press). Further, we have demonstrated that temporary inactivation of one or a few modules results in loss of on-line memory for particular target locations (Sawaguchi and Goldman-Rakic, 1991). These and other results

provide strong evidence at a cellular level that neurons in dorsolateral areas 46 and 8A are dedicated by content—even at the level of specific visuospatial coordinates. The same neuron responds to the same location and guides the same directional response, trial after trial,

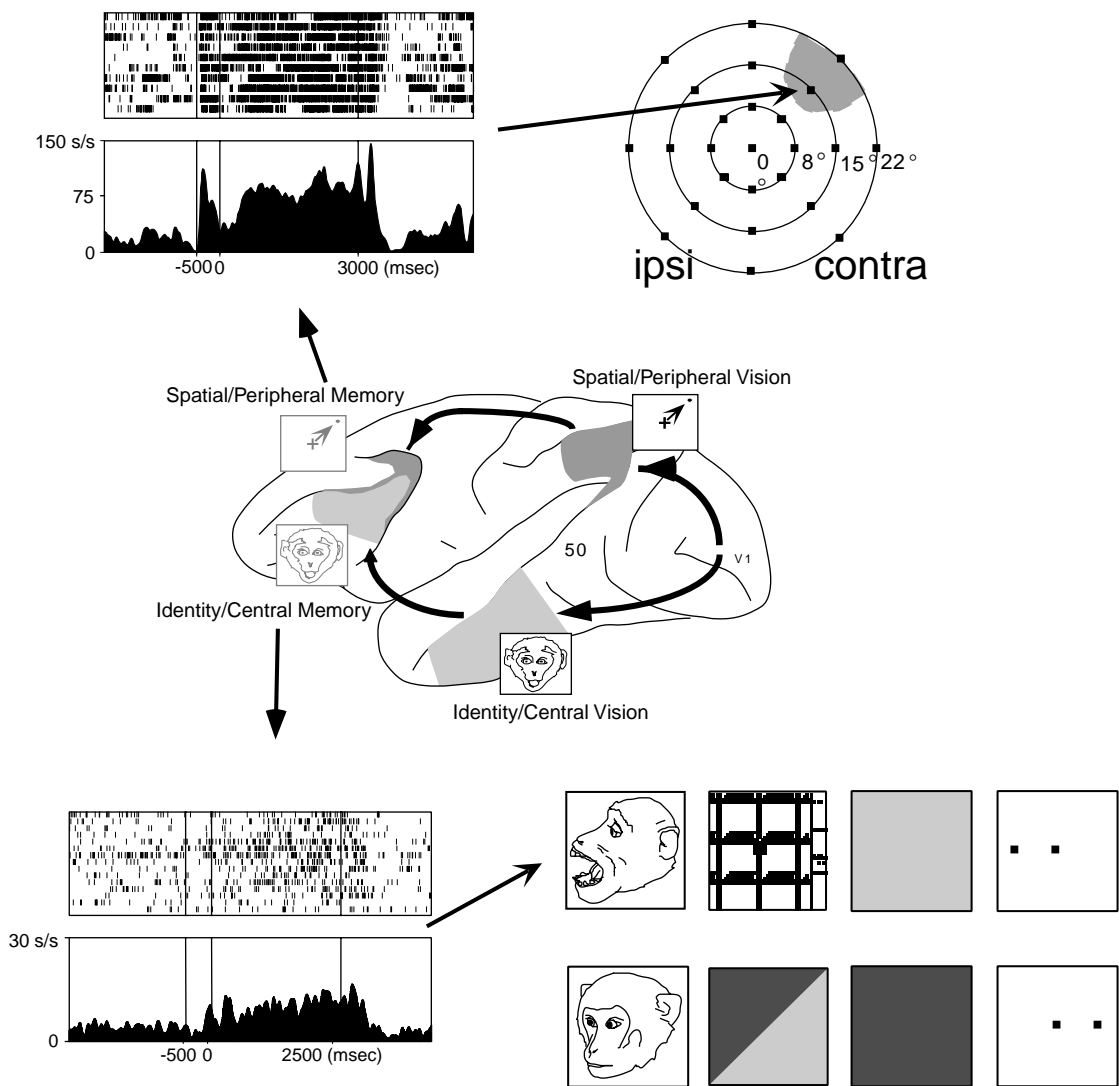

FIGURE 50.2 Multiple memory domains in the monkey prefrontal cortex. The dorsolateral area around the principal sulcus and anterior arcuate is important for spatial working memory, whereas the inferior convexity of the prefrontal cortex mediates identity working memory. *Upper*: The neuron shown was activated in the cue, delay, and saccade periods whenever the monkey had to respond to the target presented at the two most peripheral locations 45° above the horizontal meridian in the visual field contralateral to the recording electrode. The same neuron was not activated for any other targets during the delay period. The trial by trial rastergram shows neuronal activity with time in milliseconds represented on the ordinate axis for one location in the cell's memory field and the spike density function (sdf) represents the averaged activity across all trials (the scale of the sdf is in spikes per second). In both the rastergram and the

spike density function, the first vertical line indicates onset of the visual cue, the second vertical line indicates offset of the visual cue and beginning of the delay period, and the third vertical line indicates offset of the central fixation point and the monkey's signal to make a saccade to the location of the previously presented cue. *Middle*: A lateral view of the monkey brain with the temporal lobe and parietal lobe visual streams and their extension into the prefrontal cortex. *Bottom*: A neuron activated in the delay whenever the stimulus was a picture of a particular face during a working memory task; the same neuron was unresponsive to other memoranda (another face, four color patterns, and two peripheral spots of light), or in relation to direction of response (13° left or right). Conventions are as in the upper panel, with the face and pattern stimuli presented foveally and signaling a 13° saccade to the left or right of the fixation point.

and each location in the visual field is represented by a cohort of neurons in the dorsolateral prefrontal cortex.

Although there are significant constraints on the information processing machinery of prefrontal cortex, this

does not mean that a prefrontal neuron's sensory, mnemonic, and response-related activity is immutable. Within this modular architecture, mechanisms exist for plasticity in the neurons' responses to changing events. In particular, the memory fields of prefrontal cortex are

subject to modulation by neurotransmitters, such as dopamine, serotonin, and the inhibitory neurotransmitter, gamma-amino-butyric acid (GABA). Examination of the memory fields of neurons in vivo shows that the mnemonic process can be sculpted by a combination of actions at the soma of a pyramidal cell (Rao, Williams, and Goldman-Rakic, 1999), by serotonergic actions at the level of 5HT2 receptors on its proximal dendrite (Jakab and Goldman-Rakic, 1998), and by D1 dopaminergic action on the spines, which are the portion of the cell triggered by excitatory input (Williams and Goldman-Rakic, 1995). These studies show that physiologically realistic changes in the availability of dopamine or serotonin can alter dramatically the tuning of a “working

memory” neuron and can either attenuate or enhance the response magnitude. By revealing basic mechanisms of neural plasticity, these findings have the potential to form the groundwork for a rational approach to drug design for cognitive enhancement in aging and in disease (Goldman-Rakic et al., 1996; Goldman-Rakic, 1997).

Network specificity: Neuronal activity patterns in macaque prefrontal and posterior parietal cortex during spatial working memory performance

The aforementioned data identify the dorsolateral prefrontal cortex as a critical element in a neural system that uses working memory to hold specific items of spatial in-

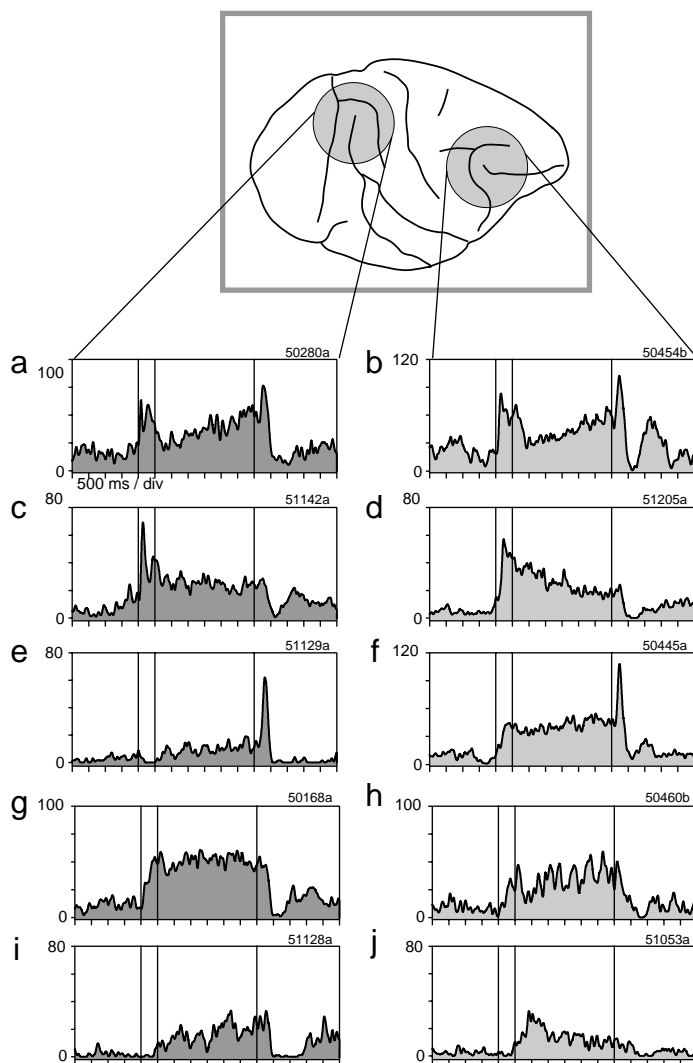

FIGURE 50.3 Similarity of delay period activity between single neurons in posterior parietal area 7ip (left column) and prefrontal area 8a (right column) during oculomotor-delayed response (ODR) performance. The spike density functions are as in the upper panel of figure 2 and represent the optimal location for each neuron. Delay period activity was observed in both areas in combination with greater bursts of activity during

cue and saccade periods (a, b), during just the cue period (c, d), or the saccade period (e, f). Delay period activity without conspicuous bursts of activity also was seen during cue and saccade periods, beginning during the cue period (g, h), or after cue offset (i, j). All neuronal activity patterns were recorded from neurons in both cortical areas. (From Chafee and Goldman-Rakic, 1998.)

formation on line. Although Walker's area 46 and adjacent 8A have been identified specifically with this process, dissections of these broad areas undoubtedly will reveal further subspecializations consistent with how subregions of these areas receive distinct projections from posterior parietal cortex (Cavada and Goldman-Rakic, 1989). Further, recent results demonstrate that the neural system supporting working memory capacity cannot reside wholly within the prefrontal cortex but extends beyond it to involve and in fact require interactions with other cortical areas. Among these is the posterior parietal cortex, with which the dorsolateral prefrontal cortex is connected anatomically directly (Petrides and Pandya, 1984; Schwartz and Goldman-Rakic, 1984; Andersen, Asanuma, and Cowan, 1985; Barbas and Mesulam, 1985; Barbas, 1988; Cavada and Goldman-Rakic, 1989; Andersen et al., 1990a; Schall et al., 1995; Stanton, Bruce, and Goldberg, 1995; Tian and Lynch, 1996).

Previous single-unit recording studies of the prefrontal and parietal cortices have been carried out in separate studies of different animals, different methods, and different delay periods (Gnadt and Andersen, 1988; Andersen et al., 1990b; Colby, Duhamel, and Goldberg, 1996; Mazzoni et al., 1996; Snyder, Batista, and Andersen, 1997). To compare the nature and incidence of different neuron firing patterns, we have alternately recorded from prefrontal area 8A and parietal area LIP within the same hemisphere of the same animals. Recording from both areas in the same monkeys eliminates any confusion caused by individual differences between animals and methods that could be misinterpreted as differences between areas. Using this approach, we examined parietal and prefrontal neurons that significantly changed their firing rate during the cue, delay, or saccade periods of the ODR task (Chafee and Goldman-Rakic, 1998). Interestingly, task-related neuronal activities were remarkably similar in both areas. Cue period activity in the prefrontal and parietal cortices exhibited comparable spatial tuning and temporal duration characteristics, taking the form of phasic, tonic, or combined phasic/tonic excitation in both cortical populations. Neurons in both cortical areas exhibited sustained activity during the delay period, with nearly identical spatial tuning (26.8° in prefrontal and 26.3° in parietal). The various patterns of delay period activity—tonic, increasing, or decreasing, alone or in combination with phasic responses during cue or saccade periods—also were similar in both cortical areas (figure 50.3). Finally, similarities in the two populations extended to the proportion and spatial tuning of presaccadic and postsaccadic neuronal activity occurring in relation to the memory-guided saccade. Previous findings in the parietal cortex are in

accord with this result (Gnadt and Andersen, 1988; Andersen et al., 1990b; Barash et al., 1991a; Barash et al., 1991b; Gnadt and Mays, 1995; Colby, Duhamel, and Goldberg, 1996; Mazzoni et al., 1996; Bracewell et al., 1996). They also are supported by 2-deoxyglucose studies of cortical metabolism in primates during working memory tasks (Friedman and Goldman-Rakic, 1994; figure 50.4). Therefore, numerous findings in nonhuman primates support and extend evidence for a faithful transmission of receptive field properties and virtually every other dimension of task-related activity observed when the parietal and prefrontal cortices are recruited to a common task. This striking similarity attests to the principal that information shared by a network of *association* areas, for example, a prefrontal region and a sensory association area with which it is connected, is domain specific.

Areal specificity: Multiple working memory domains in the prefrontal cortex

One of the major questions confronted by our field is that of how cortical function maps onto association cortex. In simple animals, such as most invertebrates, behavioral plasticity and learning reflect changes in sensory and motor neurons. A simple way to build a richer behavioral repertoire with more flexible responses to the environment would be for neurons connected, directly or transynaptically, to sensory receptors and motor effectors to mediate behavior in a flexible but still domain-specific fashion. For example, in the case of holding a stimulus on line, a neuron with visual selectivity could continue firing after the offset of the stimulus and thus mediate the memory of the recently seen object. In this last section, we review recent evidence, based on anatomical and physiological observations, that subregions of the dorsolateral prefrontal cortex may be organized according to informational domain and that each domain mediates on line processing (Goldman-Rakic, 1987).

To examine the issue of domain specificity, we have carried out a series of single-unit recordings from neurons in areas 12/45 that lie just below the principal sulcus on the inferior convexity of the prefrontal cortex (Wilson, Ó Scalaidhe, and Goldman-Rakic, 1993; Ó Scalaidhe, Wilson, and Goldman-Rakic, 1997). These areas were selected as likely candidates for processing nonspatial information—that is, color and form—because lesions of this area produce deficits on tasks requiring memory for the color or patterns of stimuli (Passingham, 1975; Mishkin and Manning, 1978) and the receptive fields of the neurons in this area, unlike those in areas 46 and 8 on the dorsolateral cortex, represent the fovea

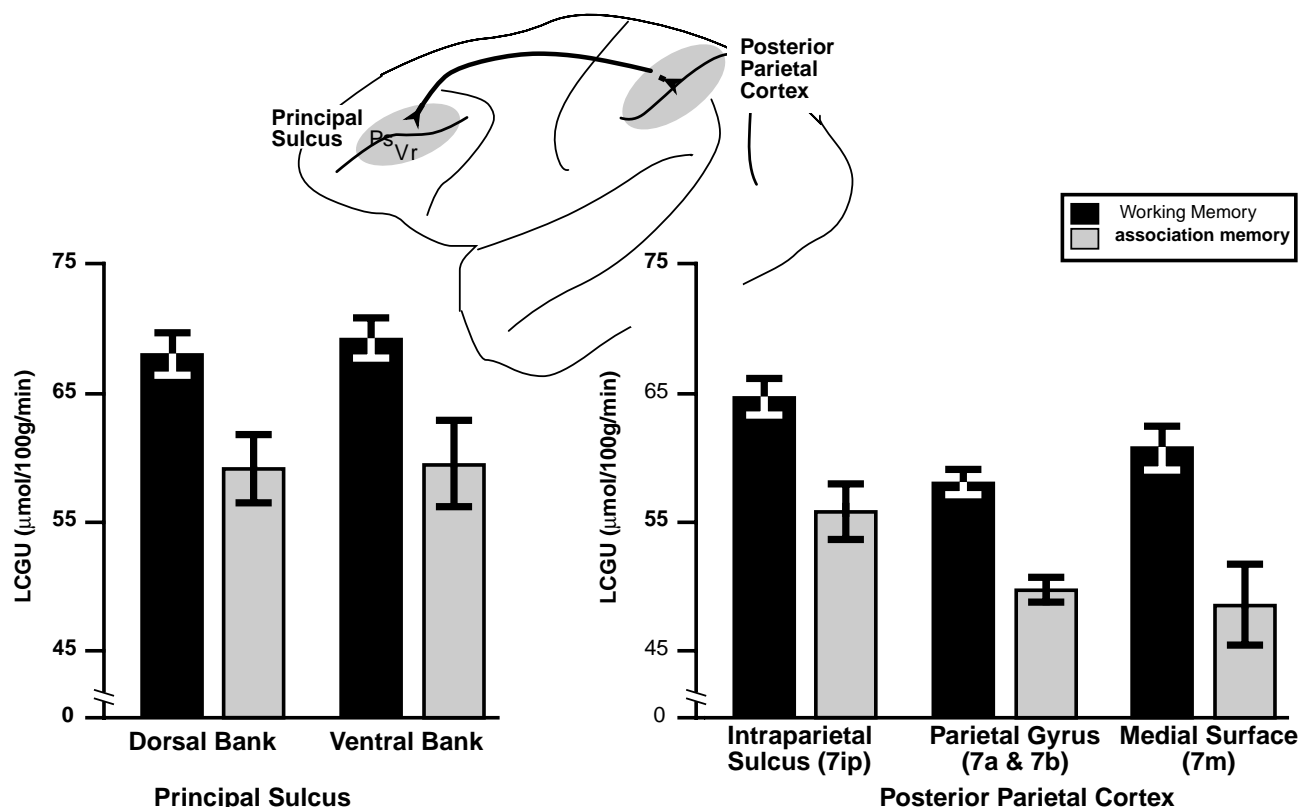

FIGURE 50.4 Mean local cerebral glucose utilization (LCGU) rates in the principal sulcus and posterior parietal cortices of monkeys performing spatial working memory and control (associative and sensorimotor) control tasks. Mean LCGU is enhanced in the working memory group (solid bars) by 15% or

more compared with the same areas in monkeys performing the control tasks (hatched bars). The overlying schematic underscores the anatomical findings of Cavada and Goldman-Rakic (1989) showing the reciprocal connections between these two areas (Goldman-Rakic, Chafee, and Friedman, 1993).

(Suzuki and Azuma, 1983), the region of the retina specialized for the analysis of fine detail and color. Therefore, we used objects and faces as stimuli/memoranda and presented them centered on a point that the monkeys visually fixated, both in “picture” tasks (figure 50.1B) and delayed-response formats (figure 50.1A). Neurons were tested both with spatial and nonspatial tasks to determine whether the neurons had directional preferences, object/face preferences, or both. We discovered that the neurons in the inferior convexity are highly responsive to the sight of complex stimuli, such as pictures of faces or specific objects. Often, selective responses continued or began after the offset of the visual stimuli, in both trained and untrained monkeys, suggesting that delay-period activity reflects an intrinsic property of the neurons’ responses. Neurons exhibiting selective neuronal activity for objects or faces are found disproportionately (objects) or almost exclusively (faces) in or around area 12 on the inferior convexity of the prefrontal cortex (figure 50.2, lower), beneath the principal sulcus, whereas neurons that responded selectively in the spatial tasks are concentrated in the dorsolateral cor-

tical regions, where spatial processing has been observed in previous studies. The areas from which face or object selective neurons are recorded are connected directly with area TE in the inferotemporal cortex, which is a major component of the ventral pathway for object vision (Ungerleider and Mishkin, 1982) and an area rich in cells that respond to the features of visual stimuli, including faces (e.g., Gross, Rocha-Miranda, and Bender, 1972; Rolls and Baylis, 1986). These results suggest that attributes of an object or face related to its identity are processed separately from those dedicated to the analysis of spatial location. Further, the specialized circuits for maintaining the identity of objects and faces in Walker’s areas 12 and 45 may process nonspatial information in a manner analogous to the mechanism by which area 46 mediates memory of visuospatial information.

Domain specificity of working memory function in human cognition

Considerable evidence for domain specificity can be found in the human imaging literature. Remarkably,

fMRI and evoked potential recording studies of working memory for faces in humans show selective activation of an inferior region of the prefrontal cortex in the human brain that appears to correspond to the areas activated by object/face stimuli in the single-unit studies of monkeys (e.g., Courtney et al., 1997; Haxby et al., 1996; Kelley et al., 1998; Allison et al., in press). Working memory for the features of objects also engages anatomically lateral and inferior prefrontal regions (Adcock et al., 1996; Cohen et al., 1994; Courtney et al., 1996; Kelley et al., 1998; McCarthy et al., 1996). The Kelley study demonstrated, furthermore, that when verbal encoding is engaged, the left inferior prefrontal cortex is activated; when visual analysis is not aided by verbal encoding, right inferior prefrontal activation is observed; and when a task can be performed by both verbal and pictorial encoding, the inferior prefrontal areas of both areas are engaged. Hemispheric lateralization of response may depend on whether faces are encoded verbally; when temporal parameters discourage verbal labeling, right hemispheric localization prevails (Grady et al., 1995). Similarly, explicit verbal processing tasks, including word generation, naming objects, and word encoding tasks, consistently invariably activate inferior, insular, or anterior prefrontal regions in the left hemisphere (Kapur et al., 1994; Kapur et al., 1996; Raichle et al., 1994; Demb et al., 1995; Baker et al., 1996; Kelley et al., 1998; Fiez et al., 1996; Paulesu, Firth, and Frackowiak, 1993; Price, Wise, and Frackowiak, 1996). By contrast, the middle frontal gyrus, where area 46 is located, has been activated consistently as human subjects access visuospatial information from long-term storage or immediate experience through representation-based action (e.g., Baker et al., 1996; Gold et al., 1996; Goldberg et al., 1996; Nichelli et al., 1994; McCarthy et al., 1994; Owen, Evans, and Petrides, 1996; Smith, Jonides, and Koeppe, 1996; Sweeney et al., 1996). These findings indicate that, as in monkeys, domain specificity exists in humans. Indeed, the human brain contains a novel form of domain specificity—hemispheric specialization based on language.

Other studies (Owen et al., 1998) have failed to dissociate object and spatial working memory, and some, including our own, have shown overlapping right middle frontal activation for object and spatial processing. It perhaps is instructive that in both monkeys and humans, the best regional specialization for nonspatial stimuli has been observed when faces are used as stimuli (Ó Scalaidhe, Wilson, and Goldman-Rakic, 1997; Courtney et al., 1996; Haxby et al., 1996). There are a few factors that may explain this. First, faces have been of great ecological significance to both humans and rhesus monkeys, and therefore, neural responses to faces are likely

to reflect the functional design of the nervous system. Second, faces, unlike many putatively nonspatial artificial stimuli, are spatially constrained with eyes, ears, nose, mouth, and hair in a fixed spatial relationship to each other. Unlike faces, letters, abstract figures, geometric figures, and computer-generated shapes can be encoded partly or largely by a spatial strategy (e.g., a set of parallel ellipses at a 45° angle). Many of these stimuli also lack characteristics of real objects, such as color, texture, and depth cues. With respect to the spatial system, the practically obligatory ecological relationship between spatial vision and movement (Goodale and Milner, 1992) suggests that the best isolation of spatial regions is seen by using visuo-movement tasks. Accordingly, the area most active in spatial working memory appears to be in and immediately anterior to the frontal eye fields both in macaque and human (Ó Scalaidhe and Goldman-Rakic, 1993; Courtney et al., 1998). The difficulty of interpreting negative findings notwithstanding, the functional architecture suggested by physiological and lesion studies in monkeys appears to be supported by findings from imaging studies in humans. The superior to inferior localization of spatial and object processing and the lateralization of verbal processing in imaging studies of human cognition support a multiple domain hypothesis of prefrontal functional architecture, which is based on network organization.

As to the remaining expanse of prefrontal areas, less is known. The evidence from recent studies of the medial wall and orbital surface indicate that these regions of the frontal lobe are compartmentalized similarly as to informational domain. The anatomical connections of the dorsomedial prefrontal cortex suggest that it is involved in high-order movement-related cognition (Dum and Strick, 1991). Baylis and colleagues and others have mapped a taste area in the caudolateral orbitofrontal cortex near an area concerned with olfaction (Baylis, Rolls, and Baylis, 1995; Tanabe, Ooshima, and Takagi, 1974; Carmichael and Price, 1995). Studies of orbital lesions in humans have revealed an autonomic pattern of deficits (Damasio, Tranel, and Damasio, 1991) as well as deficits in real world social contexts (Grattan et al., 1994; Eslinger, Grattan, and Geder, 1995). In addition to being domain specific, whether these prefrontal regions mediate on-line memory functions remains an issue for further investigation.

Conclusion

As aforementioned, neurophysiological and neuropsychological studies in nonhuman primates and functional imaging studies in humans demonstrate the organization of the prefrontal cortex into domains consonant with its

anatomical connections. This suggests that organisms that primarily respond to sensory input and motor output may have developed the capacity to hold information on line by extending sensory responses to persist after the termination of sensory stimulation and thereby to flexibly instruct responses mediated by stored information, that is, information not available in the immediate stimulus environment. Ultimately, the elaboration of this process may have contributed to the human capability to behave independent of their immediate stimulus milieu and thereby to flexibly prepare for and think about future consequences of their actions.

51 Learning and Memory in the Inferior Temporal Cortex of the Macaque

CYNTHIA A. ERICKSON, BHARATHI JAGADEESH, AND ROBERT DESIMONE

ABSTRACT The goal of visual processing is more than just to parse the pattern of active cones on the retina into representations of objects. Within the visual system, the neural representations of objects also are influenced strongly by experience and behavioral relevance, both of which involve cortical mechanisms for memory. In this chapter, the authors describe how object representations are modulated by both top-down mechanisms for working memory and bottom-up mechanisms for learned salience, processes that serve to extract behaviorally relevant objects out of cluttered scenes. Recent work also is described on long-term modification of object representations by associative memory, which serves to alter the neural representations of behaviorally relevant objects so that they reflect associations in time.

Pictures paint far more than a thousand words. Processing the huge quantities of raw data in a cluttered visual scene to recognize a particular object is profoundly difficult by machine but is accomplished rapidly and easily by our visual systems. The visual system takes a two-pronged approach to solving these computational problems. The first prong is an extremely effective mechanism for processing visual information. The second prong is concentration of processing resources on behaviorally relevant objects. These are both expressed in the transformation of visual information through successive stages of computation in the brain. In the highest stages of visual processing, the visual code reflects increasingly complex characteristics of the visual image, and the code is modified by influences not intrinsic to the visual stimulus, such as behavioral context, relevance, and experience.

The synthesis of these processes can be seen in the neuronal responses recorded in the inferior temporal (IT) cortex, at the end of the ventral, or “what” stream of visual processing (Gross, 1994). In this review, we focus on the portion of the IT cortex known as the perirhinal cortex. Although the perirhinal cortex shares many properties with surrounding cortices that also are con-

sidered part of the IT cortex, it appears to play an even greater role in mnemonic functions. Lesion studies in monkeys have shown that damage restricted to the perirhinal cortex cause memory impairment, including severe deficits of visual recognition (Gaffan, 1994; Meunier et al., 1993; Meunier et al., 1996; Murray and Mishkin, 1986; Suzuki et al., 1993; Zola-Morgan et al., 1989; Zola-Morgan et al., 1993) and association memory (Murray, Gaffan, and Mishkin, 1993).

Thus far, there is no evidence for a separate class of perirhinal neurons exclusively involved in “memory” functions. Rather, the mnemonic properties of perirhinal neurons exist simultaneously with their stimulus-selective properties. An example of stimulus selectivity for a representative perirhinal neuron is shown in figure 51.1. The histograms in the figure show the average responses of a neuron to complex color stimuli presented on a computer display while the monkey maintained fixation on a spot at the center of the display. The stimuli that elicit large responses should not be considered the “optimal” stimuli for the cell, in any sense. Although the cells in the posterior portion of the IT cortex may respond to identifiable stimulus features (Desimone et al., 1984; Tanaka, 1993), it often is difficult to identify a feature dimension that explains the selectivity of a neuron in perirhinal cortex for a given set of stimuli (Erickson and Jagadeesh, unpublished observations, 1998). However, the responses of perirhinal neurons can discriminate among complex sets of stimuli because the cells respond in a graded fashion to more than one stimulus. The difference in response between two different stimuli (e.g., the picture of the camel and the painting of the woman in figure 51.1) can be quite large.

The visual responses of many neurons in perirhinal cortex are modulated by the behavioral significance of the stimuli, which typically is established through experience. The major types of memory-related influences observed to affect the responses of perirhinal neurons are illustrated in figure 51.2. Some of these influences may require “top-down” feedback from other cortical areas, for example, cortical areas that mediate working memory. Feedback mechanisms may be the cause of

CYNTHIA A. ERICKSON, BHARATHI JAGADEESH, and ROBERT DESIMONE Laboratory of Neuropsychology, National Institute of Mental Health, National Institutes of Health, Bethesda, Md.

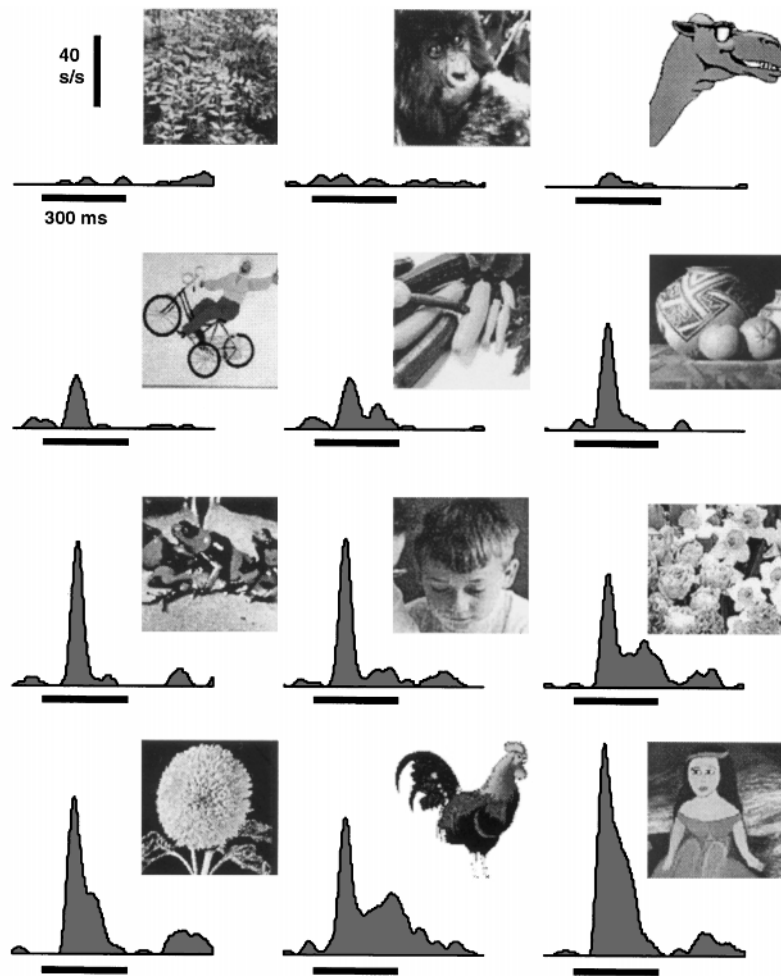

FIGURE 51.1 Example of stimulus selectivity in the perirhinal cortex. Response of a single neuron in the perirhinal cortex to presentation of 12 different complex visual images at the fovea

while the monkey fixated on the screen. The histogram is generated by averaging the response of the neuron to multiple presentations of individual stimuli.

maintained activity during the delay period of working memory tasks in the IT cortex as well as enhanced responses when behaviorally relevant stimuli appear in a scene (see top two rows of figure 51.2). These influences, including delay activity, and biasing were discussed in the previous edition of this book (Desimone et al., 1995), and have been reported in several original studies, including Chelazzi and associates (1993) and Miller and colleagues (1993). Other mnemonic influences on perirhinal responses appear to be caused by “bottom-up” mechanisms, i.e. mechanisms that are intrinsic to extrastriate cortex itself. Repetition suppression as well as mechanisms for learned salience and associative memory are examples of processes that may be intrinsic to IT cortex (see bottom three rows of figure 51.2). Repetition suppression was discussed in the previous edition of this book (Desimone et al., 1995). In this review, we describe one example of top-down biasing of signals in the perirhinal cortex and compare and contrast that with bot-

tom-up mnemonic influences on perirhinal responses. These influences serve, in part, to extract behaviorally relevant objects from scenes and to “mold” the representations of objects to reflect meaningful associations. We have been able to identify the neural basis of some of these cognitive effects by recording the activity of single neurons in the perirhinal cortex while monkeys performed memory tasks designed to tax different aspects of visual memory.

Selection of relevant objects by means of top-down feedback mechanisms

A good example of how top-down feedback to perirhinal cortex may be used to select objects from a scene comes from studies using the visual search task (Chelazzi et al., 1993, 1998). In those studies, while the monkey maintained fixation, a cue stimulus was presented at the center of gaze, followed by a blank delay period. At the

	A neuron that initially responds to	After experience with or instruction about	Now responds to
Delay/maintained activity (working memory, attention)			
Bias/enhancement (working memory, attention)	 +/or 		
Repetition suppression (priming)	 +/or 		
Acquired salience (perceptual learning, attention, popout)	 +/or 	 + R	
Stimulus correlations (associative memory)		 + 	 or 

FIGURE 51.2 Schematic diagram of memory mechanisms observed in temporal cortex. Delay/maintained activity and bias/enhancement are two examples of top-down processes discussed in the section on selection of relevant objects by means of top-down feedback mechanisms. Repetition suppression, a bottom-up process, refers to the reduction in response that oc-

curs with repeated presentations of the same stimulus. Acquired salience and stimulus correlations also are examples of bottom-up processes, detailed in the section on selection of relevant objects by means of stimulus salience and the section on associative learning, respectively.

end of the delay, an array of two to five choice stimuli was presented peripherally, and the monkey was rewarded for making a saccadic eye movement to the target stimulus, that is, the choice stimulus that matched the cue stimulus (figure 51.3A). The identity and location of the target stimulus varied from trial to trial. The array was composed of one “good” stimulus (effective in driving the cell when presented alone) and one or more “poor” stimuli (ineffective in driving the cell when presented alone). Thus, one could compare the response to an array consisting of both good and poor stimulus on trials when the good stimulus was the target stimulus with the same array of stimuli when one of the poor stimuli was the target stimulus.

There were two critical time periods during the trial. The first was during the delay period, while the animal was gazing at a blank screen, preparing to find the target stimulus in the array. Most neurons showed higher activity during the delay after a good stimulus presented as a cue than after a bad stimulus presented as a cue. This activity could not have been merely a prolonged response to the cue stimulus because it also was higher during the period *preceding* the presentation of a good cue, if the animal expected it to occur. This was found in cases in which the same cue stimulus was used for a block of trials. Thus, the delay activity between presentation of the cue stimulus and choice array suggests a top-down, or feedback, bias in favor of neurons coding the relevant stimulus. In this situation, the de-

lay activity in the perirhinal cortex is very similar to the stimulus-specific delay activity found in numerous studies of working memory in the prefrontal cortex (di Pellegrino and Wise, 1991; Fuster and Alexander, 1971; Kojima and Goldman-Rakic, 1982; Miller, Erickson, and Desimone, 1996; Wilson, Scalaidhe, and Goldman-Rakic, 1993).

The second critical period was when the choice array was presented. Within 150 to 200 ms of array onset, the responses of most neurons were determined almost exclusively by the target stimulus. If the target was the good stimulus, the response to the array was equal to the response to the good stimulus presented alone, whereas if the target was the poor stimulus, the response was suppressed almost to the level of response to the poor stimulus alone. Thus, the neurons responded as though only the target stimulus was present inside the receptive field. These effects occurred approximately 100 ms before the eye movement to the target stimulus was initiated. Overall, the results support a “biased competition” model of attention, according to which (1) objects in the visual field compete for representation in the cortex, and (2) this competition is biased in favor of the behaviorally relevant object by virtue of top-down feedback from structures involved in working memory. In the next section, we consider how relevant objects may be selected from a scene based on longer-term experience with that object.

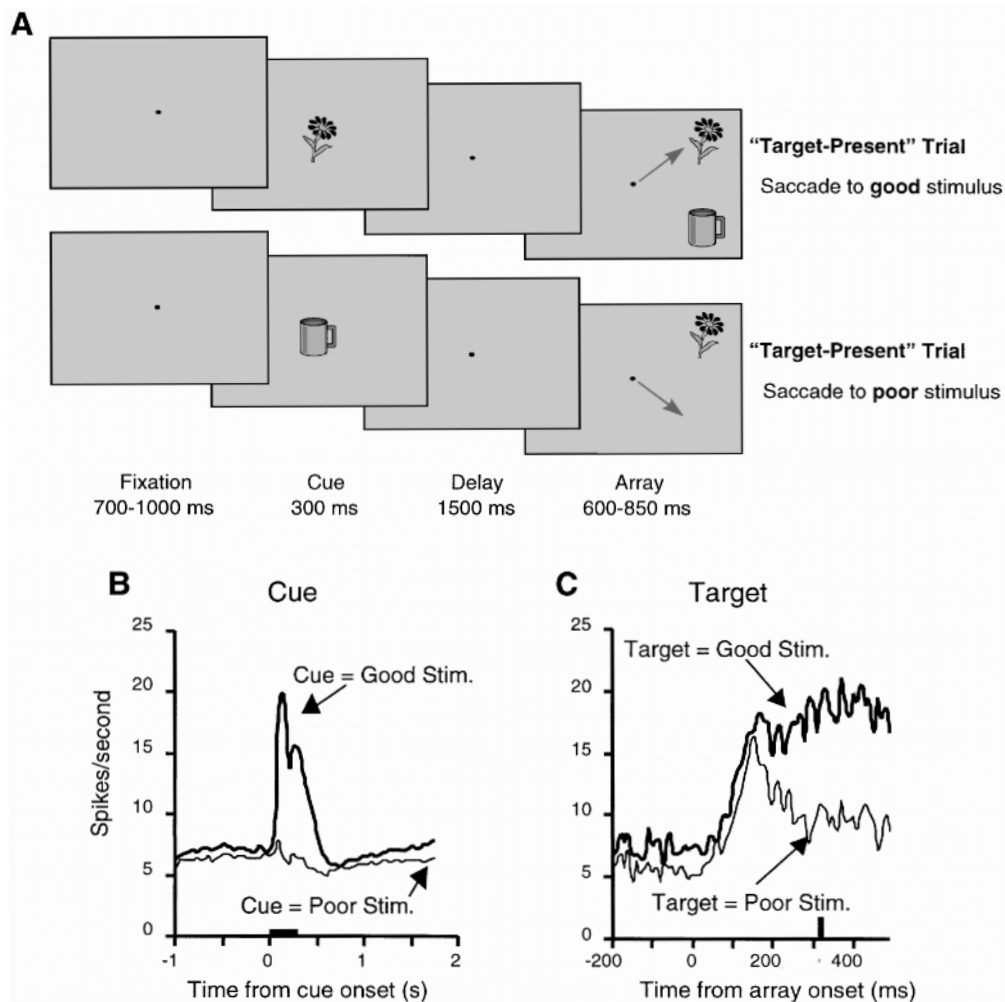

FIGURE 51.3 Responses of neurons in the inferior temporal (IT) cortex in a visual search task, with search arrays confined to the contralateral visual field. (A) Schematic representation of the task. A cue stimulus was presented at the start of the trial, followed by a delay, and then an array of stimuli. The array contained a target stimulus matching the cue stimulus, and the monkey was rewarded for making a saccade to it. On some trials, the cue-target was a good stimulus for the neuron (top row), and on other trials it was a poor stimulus for the neuron (bottom row). Relative locations of the good and poor stimulus in the array varied randomly from trial to trial. (B) Response of a population of 88 individually recorded IT neurons at the time of the cue stimulus presentation. Trials with a given cue

stimulus were run in blocks. Neurons showed higher maintained activity both before and after the cue stimulus presentation on trials when the cue stimulus was a good stimulus for the neurons. (C) When the choice array was presented, the same neurons shown in (B) initially responded well, regardless of which stimulus was the target stimulus. By 170 ms after stimulus onset, responses diverged dramatically, depending on whether the target stimulus was the good or poor stimulus for the neuron. This target-selection effect occurred well in advance of the saccade to the target stimulus, indicated by the small vertical bar on the horizontal axis. (Adapted from Chelazzi et al., 1998.)

Selection of relevant objects by means of learned stimulus salience

Often, objects are selected from scenes even when we are not searching actively for them and have no prior expectation that they even will be present. For example, a bright red bird on a green tree immediately attracts attention, whereas a camouflaged brown sparrow in a brown field does not attract attention. This kind of salience generally is believed to reflect low-level process-

ing and segmentation of visual scenes. In terms of the biased competition account, objects that differ from their backgrounds have a greater competitive advantage. However, the salience of an object also is affected by its relevance for behavior. Learned stimulus salience is acquired through experience with the object. For example, one's attention may be grabbed by the unexpected presence of one's spouse in a scene.

We tested for the kind of neural changes that may result from learned salience by repeatedly rewarding monkeys

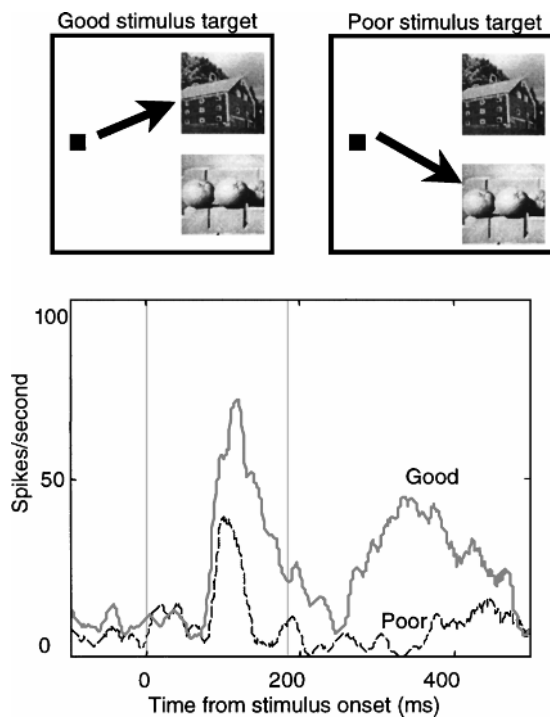

FIGURE 51.4 Responses from an individual neuron in the perirhinal cortex in a learned salience task. The array consisted of a good and a poor stimulus for the neuron (based on prior testing with individual stimuli), and the animal was rewarded for making an eye movement to the “positive” stimulus. Responses are shown for a block of trials in which the good stimulus was consistently the positive stimulus for the neuron (solid line) compared with a block of trials in which the poor stimulus was the positive stimulus for the neuron (dashed line).

for making a saccade to a target stimulus in an array. This task was similar to the visual search task described in the previous section, except that there was no cue at the start of the trial. The monkey simply had to learn through trial and error that making an eye movement to the target stimulus in the array led to reward and that making an eye movement to any other stimulus did not lead to a reward. As in the search task, the array consisted of one good stimulus and one poor stimulus for the neuron, determined by prior testing with each stimulus individually. Once the monkey had learned to select the target stimulus reliably, the association between stimulus and reward was reversed. Thus, the previously rewarded target stimulus became an irrelevant distracter, and the previous distracter now was associated with reward. For each neuron, we compared the neuron’s responses to the scene when the good stimulus was the rewarded target stimulus versus when the poor stimulus was the rewarded target stimulus.

A representative neuron is illustrated in figure 51.4. In this figure, the solid line shows the response to the visual scene when the good stimulus was the behaviorally rele-

vant target stimulus, and the dashed line shows the response to the visual scene when the poor stimulus was the behaviorally relevant target stimulus. The monkey made the saccade to the target stimulus approximately 200 ms after stimulus onset, on average. Before the saccade occurs, the visual scene was identical in both conditions; the only difference was the behavioral relevance of the stimulus. The figure shows that when the good stimulus was the target stimulus, the response of the neuron remained high throughout the trial. However, when the poor stimulus was the target stimulus, the response to the same array was suppressed strongly. This difference (“target effect”) occurred approximately 100 ms before the eye movement to the target stimulus was made.

The results in the learned salience task were very similar to those in the visual search task described previously except that there was no evidence for the differential “delay” activity found in the visual search task before the presentation of the array. In the learned salience task, the activity of neurons was the same before the presentation of the array, regardless of which stimulus was the target stimulus. This suggests that, unlike in the search task, there was no top-down feedback biasing activity in favor of the expected target in this task. Rather, we suggest that the bias in favor of the target resulted from a change in the competitive interactions between target and nontarget stimulus within the visual cortex itself.

Additional evidence in favor of the idea of a “bottom up” modification of the neurons’ response to the scene, rather than the trial by trial influence of a top-down feedback selection process, came from examining data on error trials. On these trials, the animal selected and made an eye movement to a stimulus in the array, as on correct trials; however, on the error trials, the stimulus was not the one that had been paired repeatedly with reward. If the target effect were due to a selection mechanism actively modulating the responses of IT neurons, it still should have been found in the error trials, but linked to the stimulus that was selected by the animal rather than the stimulus that had been associated previously with reward. Instead, we found that there was no difference in response to the array, regardless of whether the good or poor stimulus was selected. The target effect simply was missing on the error trials. This suggests that the effects of learning failed to be expressed in neuronal responses in the IT cortex on these trials, and therefore, the information needed for a correct decision was not available to the animal.

To rule out conclusively the possibility of active feedback biasing IT activity in favor of the target stimulus and causing the target effect in the learned salience task, we conducted a control experiment. For this control, we

trained the animals on 10 concurrent pairs of stimuli used in the choice arrays. We reasoned that 10 pairs should exceed the capacity of working memory and would prevent the animal from having any expectation of which target stimulus would appear on any given trial. The animal was trained on the 10 pairs during several weeks of training before the first recording session. Although this strategy precluded working memory, we nonetheless found the same target effect that we found in the first learned salience experiment—that is, the response to the array was determined by the target stimulus, the response to the nontarget being suppressed. This was strong evidence against active feedback and in favor of learning-induced changes in the extrastriate cortex itself.

MECHANISM OF LEARNED SALIENCE In principle, the change in response to the scene might have resulted from a combination of two underlying mechanisms. The response to the pair could be enhanced when the good stimulus is the target, or the response to the pair could be suppressed when the poor stimulus is the target. To differentiate between these two possibilities, we examined changes in the neural response to the stimulus as the monkey learned to saccade to the target stimulus in return for the reward.

The change in neuronal response with training can be seen in figure 51.5. The average response in the time around the saccade is shown for a population of neurons, in the first 10 trials, when the monkey has just started learning the task, and in the last 10 trials, when the task is well learned. During this period, the percent of correct saccades (saccades to the rewarded target stimulus) increased from 55% to 89%. The average responses in the early trials and late trials are shown separately for responses to the scene when the good stimulus was the target stimulus and for scenes when the poor stimulus was the target stimulus. The response difference between trials in which the good stimulus is the target versus when the poor stimulus is the target is significant both early and late in the session. This difference grows in size as the monkey learns to do the task and the mechanism for that growth is increased suppression in the neuron's response to the good stimulus when the poor stimulus is the target. Thus, the main effect of the training was a suppression of responses to nontarget stimuli.

The hypothetical change in the cortical circuit occurring with training is shown in figure 51.6. In the diagram, the dark circles represent neurons that respond to the picture of the house but do not respond to the picture of the oranges, and the light circles represent neurons with the opposite stimulus preference. Before training, when the visual scene is shown, neurons that respond both to houses and oranges are active. After training, the house becomes

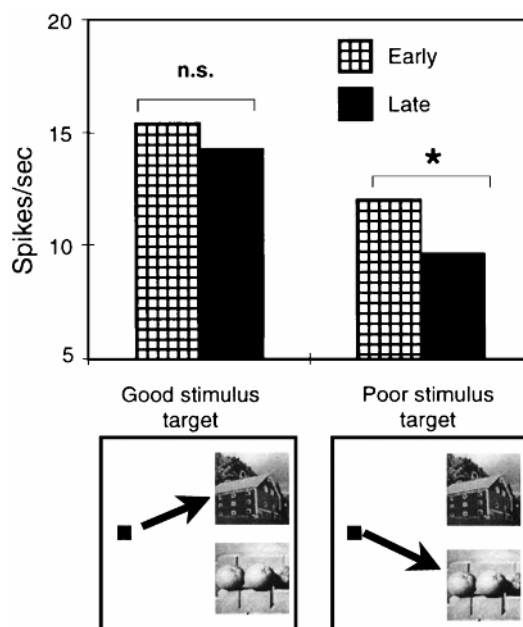

FIGURE 51.5 Response changes over trials during training session. Average in saccade interval (75 ms before saccade onset to 50 ms after saccade onset) for first 10 trials and last 10 trials for each stimulus set, when the good stimulus is the target stimulus or when the poor stimulus is the target stimulus. The difference in neural responses on early and late trials in the recording session was not significant for the good stimulus target trials. However, the difference between neural responses early and late in the recording session was significantly larger for the poor stimulus target trials ($P < .05$). Thus, responses to the good stimulus were suppressed increasingly as the poor stimulus was associated consistently with reward.

the behaviorally relevant stimulus, and the neurons that respond to the behaviorally irrelevant oranges are suppressed. If, however, the monkey is trained to saccade to the picture of oranges, the activity of those neurons remains high, but the neurons that respond to the house are suppressed. In either case, after training, the pattern of activity across the cortex selects the behaviorally relevant image from the scene.

If we look at the top panels in the figure, we see that the behaviorally relevant image is better represented in the scene because the neurons that represent the other image have been suppressed. Thus, this pattern of activity resembles that expected from traditional ideas of object salience; namely, the activity of neurons that represent the attention-grabbing objects in a visual scene is larger than that of neurons that represent less attention-grabbing objects.

Associative learning

In both the visual search task and the learned salience task, the responses of the neurons were modulated ac-

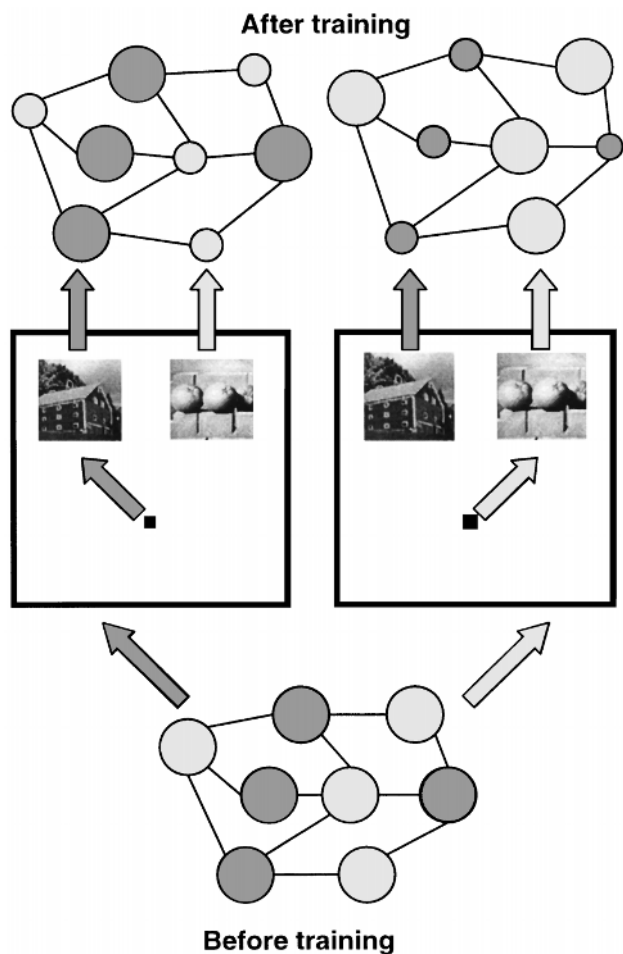

FIGURE 51.6 Schematic representation of changes in cortical circuits with training. Each filled circle represents a neuron in perirhinal cortex, and the size of the circle represents the magnitude of the neuron's firing rate. Before learning, simultaneously presented stimuli in the visual field are represented by joint activity of neurons participating in the relevant neural representations, which engage in competitive (suppressive) interactions, indicated by the links between circles. As monkeys learn that one stimulus is behaviorally relevant, the neurons representing the target stimulus attain a competitive advantage, resulting in the exclusive representation of the target stimulus in the cortex.

cording to which stimulus was selected or rewarded, but the underlying stimulus selectivity of the neurons remained unchanged. This suggests that stimulus selectivity can be conserved during the other changes that come about as a result of attention or learning. Conversely, in the example neuron from the perirhinal cortex shown in figure 51.1, it is hard to imagine a set of visual features shared in common by all the stimuli that elicited good responses. This is typical of many neurons in the perirhinal cortex. Although high-level feature sets eventually may explain the pattern of stimulus-selective responses in this cortex, it also is possible that effective stimuli share more

abstract, or temporal, associations rather than visual features per se. For example, forks and plates commonly are associated with one another, but they do not resemble each other. If the responses of perirhinal neurons reflect these more abstract types of stimulus relationships, then the responses of the neurons may be determined, at least in part, by associative learning mechanisms.

Miyashita and colleagues examined the neural mechanisms that might underlie the formation of associations between pairs of stimuli in the neurons of the perirhinal cortex. Recordings were made from neurons in the perirhinal cortex and area TE while monkeys performed a paired-associate task similar to one used to test association learning in humans (Sakai and Miyashita, 1991; Higuchi and Miyashita, 1996; Miyashita et al., 1996). They found examples of neurons that responded best to both stimuli that were associated together behaviorally. Across the population of neurons, there was a small correlation between the neurons' selectivity for the sample stimuli and their selectivity for the associated choice stimuli. Two other groups, however, using different tasks, failed to find correlated responses to paired stimuli (Gochin et al., 1994; Sobotka and Ringo, 1993).

We designed a task in which stimuli were linked temporally and in which associated stimuli could be learned quickly, within a single recording session. In this task, the monkeys learned to discriminate between eight choice stimuli concurrently. The monkey was rewarded for releasing a bar to half the choice stimuli and for continuing to hold the bar for the other half of the stimuli. One second before the choice stimulus was presented; a predictor stimulus was presented briefly (figure 51.7).

Each choice stimulus was paired with a specific predictor stimulus for most of the trials. Occasionally, we presented mismatched stimulus pairs. Monkeys had longer response latencies on these trials, indicating that they had learned to associate the predictors with the choice stimuli, although they did not need to learn the associations to perform the task. We refer to this task as the "passive association task" because in contrast to the paired associate task used by Miyashita and colleagues, it does not require active memory for paired stimuli.

The responses of single neurons were recorded from the perirhinal cortex of these monkeys while they performed the association task with stimuli in which the monkeys were familiar after 1 or more days of previous training (familiar stimuli), as well as with stimuli that the monkey had never seen before that session (novel stimuli). Some neurons were found that responded best to images that had been paired together as predictor and choice (figure 51.8). Of course, these associations between preferred stimuli may have occurred by chance. To quantify the effects, we computed the correlation

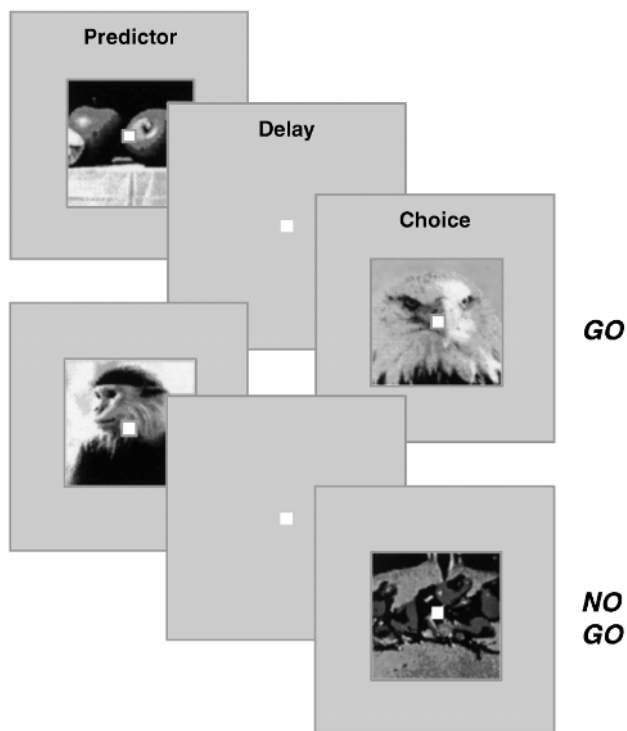

FIGURE 51.7 Schematic representation of an implicit association task. In this task, the monkeys initiated a trial by holding a bar and fixating a small spot, which they were required to fixate for the remainder of the trial. A predictor stimulus was then presented, followed, after a delay by a choice stimulus. The monkey was rewarded for releasing the bar on trials when the choice stimulus was a “go” stimulus and for holding the bar when the choice stimulus was a “no-go” stimulus.

between the responses to the paired predictor-choice stimuli for every neuron in the population. If there were no effects of learning, the average correlation should have been zero. We confirmed this by randomly shuffling the predictor-choice pairings and recalculating the correlations 1000 times. The actual correlations were not different from zero for the novel stimulus pairs but were significantly greater than zero (difference between the mean correlations, $r = 0.2$) for the familiar stimulus pairs. Thus, after 1 day of training, there is a small but measurable shift in the stimulus selectivity of the neurons, such that neurons tend to respond more similarly to stimuli that have been paired together. The fact that responses are not correlated on the first day of training, although the animals seem to have learned to associate the stimuli on the first day, suggests that the initial phase of associative learning involves structures outside the perirhinal cortex.

We observed the same basic finding in the visual discrimination task (described previously, as the multiple stimulus discrimination task) in which multiple pairs of

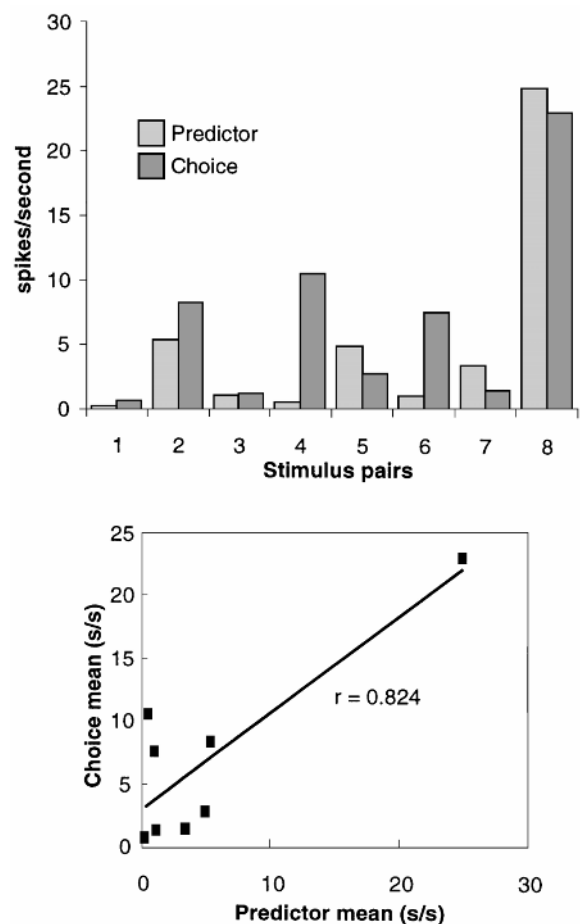

FIGURE 51.8 An example of the effects of association training on responses to stimuli-paired stimuli. Each bar represents the average firing rate of this neuron to one stimulus. The largest responses were to the predictor-choice pair number 8. The association between responses to predictors and choices was measured by plotting the mean firing rate for each predictor stimulus against its paired choice stimulus and computing a correlation coefficient (r -value). In this case, the high r -value reflects the fact that the largest responses are to paired stimuli and smallest responses also are to paired stimuli.

stimuli were presented simultaneously on the screen and the monkey had to discriminate between the two stimuli. After the monkey had learned to discriminate between the images in the multiple pairs of stimuli after several weeks of training, the responses of the neurons to individual stimuli that had been paired together was tested, by presenting the stimuli at the fovea in a passive fixation task. The mean correlation between responses to stimuli that had paired together was significantly different from chance (mean correlation = 0.2, $n = 49$). This result suggests that temporal contiguity (the simultaneous presentation of images) may be sufficient to cause associations between individual stimuli to form. A critical factor may be the requirement that the animal re-

spond separately to the different stimuli, so that it cannot treat them as a single compound stimulus.

In the versions of the associative learning task with both delayed and simultaneous presentation of the associated stimuli, the long-term changes found in the stimulus selectivity of the neurons most likely were caused by bottom-up, or intrinsic, mechanisms within the extrastriate cortex itself. However, in the version of the task with the delay between predictor and choice stimulus, we also found activity changes during the delay that may have been caused by active feedback from other structures.

DELAY ACTIVITY Many neurons exhibited stimulus-specific activity during the delay between the predictor and choice stimuli similar to what has been found in the delay period of the visual search task described in a previous section, as well as in the delay period in many previous studies of working memory (Colombo and Gross, 1994; Fuster and Jervey, 1981; Miller and Desimone, 1994; Miller, Li, and Desimone, 1991; Miller, Li, and Desimone, 1993). With novel stimuli, the magnitude of the delay activity was correlated significantly only with the responses to the predictor stimuli. The activity during the delay typically was higher after a good stimulus was used as a predictor than after a poor stimulus was used as a predictor (figure 51.9). The mean correlation between choice stimuli and the delay activity was not different from zero.

With familiar stimuli, the magnitude of delay activity was correlated with the responses to both the predictor and the choice stimuli. Thus, the relationship between the predictor stimulus and the delay activity was not different for the two experience conditions. However, the relationship between the choice stimulus and the delay activity was greater during testing with familiar stimuli than with novel stimuli. In some cases, a predictor stimulus that elicited a good response from a neuron would be followed by a high firing rate during the delay, ending with a good response to the associated choice stimulus. In these cases, the delay activity was associated not only with the stimulus that the animal had seen recently but also with the stimulus that the animal expected to see as a result of associative learning. Sakai and Miyashita (1991) also observed a correlation between delay activity and choice stimulus responses in the perirhinal cortex with familiar stimuli, although they did not test for correlations between predictor stimuli and the delay activity. We speculate that the delay activity resulting from feedback to the perirhinal cortex serves to increase the temporal proximity of predictor and choice activity and therefore may facilitate Hebbian changes in connectivity between neurons responding to the predictors and choices. These changes in functional connectivity may,

FIGURE 51.9 Example of delay activity correlated with the neuronal response to the predictor stimuli, in a neuron tested with novel predictor-choice pairs. By comparing the response during stimulus presentation (A) to the activity during the delay period (B), it can be seen that the magnitude of delay activity follows the preferences of the neuron for the predictor stimuli rather than the choice stimuli (C). This observation was confirmed by computing correlations between the mean firing rates to the stimuli and the activity during the delay period for stimulus pairs.

in turn, lead to the observed changes in stimulus selectivity after associative learning.

Conclusions

The goal of visual processing is more than the achievement of an accurate representation of the visual world. Rather, visual processing is in the service of behavior, and behavioral relevance plays a major role in how

neurons in the perirhinal cortex represent visual stimuli. Because relevance typically is determined by memory and experience with stimuli, it therefore is not surprising that sensory processing and visual memory are intertwined in such a way that they are not easily distinguishable. Neurophysiological studies identify numerous long- and short-term changes in the way that neurons in the perirhinal cortex process visual information and, thus, changes in the way that the brain “sees.”

52 Memory for Objects in Nonhuman Primates

ELISABETH A. MURRAY

ABSTRACT The hippocampus has long been thought to be critical for memory, including memory for information about objects. However, recent research on nonhuman primates shows that another region within the medial temporal lobe, the rhinal cortex (i.e., entorhinal plus perirhinal cortex), is primarily responsible for object recognition and association. It specializes in storing knowledge about objects and may serve as the kernel of a system analogous to the semantic memory system in humans. The hippocampus and the amygdala make different, secondary contributions to object memory, associating objects with events and affective valences, respectively.

Selective cerebral lesions and disconnections have long been used to identify the brain structures necessary for object recognition and association. One persistent misconception holds that the hippocampus subserves object recognition memory. This view is based, in large part, on the memory impairment found in patient H.M., who, after surgery for relief of epilepsy, became profoundly amnesic. It initially was believed and often stated that damage to his hippocampus caused the amnesia, even though his ablation included several neighboring brain structures. In recent years, the “hippocampus” has been construed generally to include nearby structures, but the basic concept has remained the same. According to this view, a group of medial temporal lobe structures, specifically the hippocampus, entorhinal cortex, perirhinal cortex, and parahippocampal cortex (figure 52.1), together constitute a single functional system subserving object recognition. Indeed, it is held that this system underlies all declarative memory, and that the greater the damage to this unified system, the greater the deficit in declarative memory (Squire and Zola-Morgan, 1991; Zola-Morgan, Squire, and Ramus, 1994). It further has been proposed that the hippocampus, in particular, mediates associative memory in the declarative domain (Eichenbaum, Otto, and Cohen, 1992) and the consolidation of information into long-term memory (Squire, Shimamura, and Amaral, 1989). In this chapter, a differ-

ent view is presented, based in part on a new method for making experimental lesions in nonhuman primates.

The use of excitotoxins, together with a stereotaxic surgical approach guided by magnetic resonance imaging (MRI), has proven to be particularly useful in studying the neural basis of object recognition and association. Magnetic resonance imaging and excitotoxins provide greater accuracy and selectivity, respectively. The former allows the direct visualization of a given structure and the accurate placement of lesion sites tailored to each subject. The latter can damage deep structures in relative isolation from superficial ones and spare fibers passing nearby or through the site of the lesion. For example, in the case of the amygdala, it is clear that traditional aspiration removal not only produces cell loss in the amygdala, as intended, but also transects efferent fibers arising from neurons located in the nearby entorhinal cortex, the perirhinal cortex, and area TE (Murray, 1992; Goulet, Doré, and Murray, 1998). Thus, the older method produces inadvertent damage, causing dysfunction in all three cortical fields.

Experiments employing the newer method show that rather than operating as a single functional unit, components of the medial temporal lobe make independent and dissociable contributions to object recognition and associative memory. One key finding is that certain types of sensory information, especially different aspects of information about objects, can be associated with one another *and* consolidated into long-term memory in the absence of the hippocampus. Thus, the hippocampus is not an obligatory part of either the associative or the information storage networks operating in the medial temporal lobe. This realization has, of course, led to a reconsideration of the function of the hippocampus, as well as the other major components of the medial temporal lobe.

Object recognition memory

The tasks most commonly employed to evaluate object recognition in monkeys are delayed nonmatching-to-sample (DNMS) and delayed matching-to-sample (DMS). In a typical DNMS task, the monkey sees a

FIGURE 52.1 Schematic diagrams of ventral (A) and medial (B) views of macaque brain hemisphere showing the locations and extents of various medial temporal lobe structures. The amygdala and the hippocampus are buried deep within the temporal lobe, whereas the rhinal (i.e., entorhinal and perirhinal) cortex and the parahippocampal cortex are located on the surface of the brain.

sample object, which it displaces to retrieve a food reward hidden underneath. After a brief interval, the monkey is allowed to choose between the sample and some different object. In DNMS tasks, the monkey must choose that “different” object to obtain another food reward; in DMS tasks, it must choose the sample object. Recognition abilities can be assessed by lengthening the interval between sample presentation and choice test or increasing the number of to-be-remembered items, or both. There are many variations of the matching tasks. In the following experiments, the task is administered with novel objects on each trial. Thus, at the choice test, the question for the monkey is “which item have you seen before?” For the purposes of the present discussion, it is this judgment, a “judgement of prior occurrence” (Brown, 1996), that we mean by *recognition*.

Using the aforementioned modern lesion techniques, one can conclude that the hippocampus plays a very limited, and probably dispensable, role in object recognition. Monkeys with combined, selective lesions of the amygdala and hippocampus perform as well as unoperated controls on tests of visual recognition (figure 52.2A), even when delay intervals as long as 40 minutes intervene between sample presentation and choice test (Murray and Mishkin, 1998). Surprisingly, in these same operated monkeys, there was a significant positive correlation between the extent of damage to the hippocampus and DNMS task performance, suggesting that the greater the hippocampal damage, the *better* the recognition (figure 52.2B). This result is in direct contrast to expectations based on studies using aspiration lesions. In those studies, combined removal of the amygdala and the hippocampus was found necessary to produce a severe object recognition impairment in monkeys (Mishkin, 1978; Zola-Morgan, Squire, and Mishkin, 1982; Saunders, Murray, and Mishkin, 1984; Murray and Mishkin, 1984), and it was believed that aspiration or radiofrequency lesions of the hippocampus alone yielded a significant impairment in visual recognition as well (Zola-Morgan, Squire, and Ramus, 1994). The present view does not deny the hippocampus a contribution to stimulus recognition per se, under some circumstances. However, the results of Murray and Mishkin (1998) show conclusively that its contribution must be minor and probably is indirect.

In contrast to selective, excitotoxic lesions of the amygdala and the hippocampus, which fail to disrupt visual recognition, removal of the rhinal cortex (i.e., the entorhinal and perirhinal cortex, cortical fields that lie ventrally subjacent to the amygdala and the rostral third of the hippocampus) yields a severe deficit (Meunier et al., 1993; Eacott, Gaffan, and Murray, 1994). Monkeys that have sustained removal of the rhinal cortex perform at near chance levels when given recognition choice tests only 60 seconds or so after presentation of the sample stimulus. The same region appears to be critical for tactual recognition as well (Suzuki et al., 1993). Thus, within the medial temporal lobe, damage to the entorhinal and perirhinal cortical fields is both necessary and sufficient to produce the severe impairments in visual recognition.

The perirhinal cortex plays a particularly central role in visual recognition. There is widespread agreement that, of the medial temporal lobe structures under discussion, damage to this region produces the most devastating effects on visual recognition (Horel et al., 1987; Meunier et al., 1993; Leonard et al., 1995). Nevertheless, it seems likely that two additional regions, the entorhinal cortex and area TE (von Bonin and Bailey, 1947), also

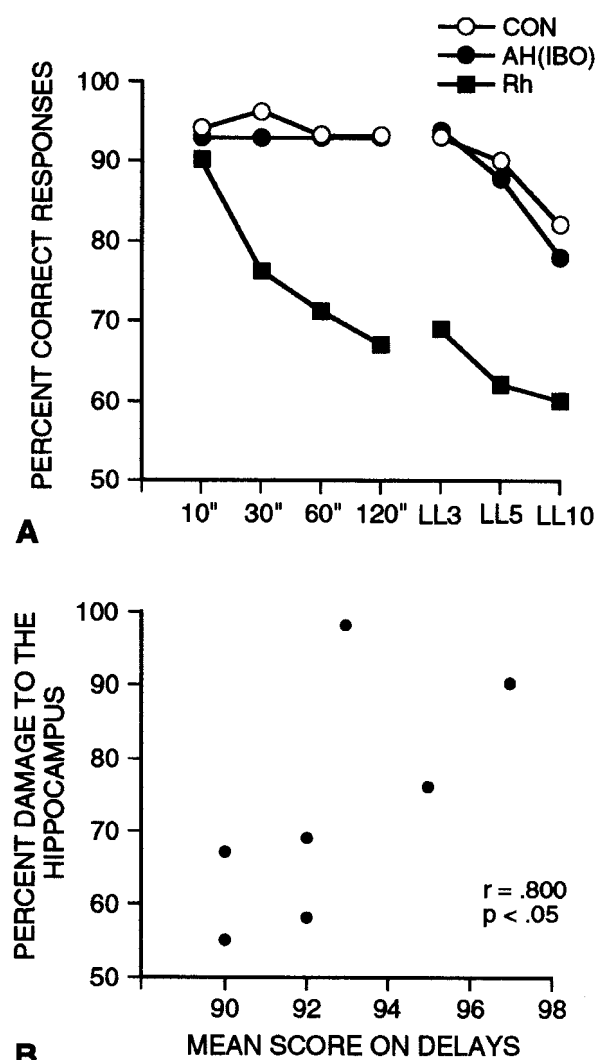

FIGURE 52.2 Effects on visual recognition, as measured by the delayed nonmatching-to-sample task, of selective, excitotoxic lesions of the amygdala and hippocampus vs. lesions of the rhinal cortex. (A) Curves on the left show the effect of imposition of increasingly longer delays (10–120 s) between sample presentation and choice test, whereas curves on the right show the results of testing with lists of 3, 5, or 10 items. Note that for the list-length testing, the delay for each item in the list is, approximately, the product of 20 s times the length of the list. *Abbreviations:* CON, unoperated controls ($N = 7$; from Meunier et al., 1993, and Murray and Mishkin, 1998, combined); AH (BO), monkeys ($N = 7$) with excitotoxic lesions of the amygdala and hippocampus (Murray and Mishkin, 1998); Rh, monkeys ($N = 7$) with aspiration removals of the rhinal cortex (Meunier et al., 1993). (B) Correlation of the extent of damage to the hippocampus with the scores on the delay portion (i.e., the 3 longer delays) of the recognition performance test for monkeys with excitotoxic lesions of the amygdala and hippocampus (Murray and Mishkin, 1998). There was a significant positive correlation, suggesting that the greater the damage to the hippocampus, the *better* the recognition. There were no negative correlations of performance test scores with damage to any structure involved in the lesion, namely the amygdala, the entorhinal cortex, the perirhinal cortex, or the subicular complex.

contribute. Three findings point to this conclusion: (1) combined entorhinal plus perirhinal cortex removal yields a greater deficit than that seen after removal of either region alone (Meunier et al., 1993); (2) combined removal of the perirhinal cortex plus area TE (see group “TE,” Mishkin, 1982) likewise produces a greater deficit than does removal of either region alone (Buckley, Gaffan, and Murray, 1997); and (3) neither combined lesions in (1) or (2) yields as great an impairment as that observed after either combined amygdala and hippocampal removals, made by aspiration (Mishkin, 1978) or combined amygdala plus rhinal cortex lesions (Murray and Mishkin, 1986). As mentioned earlier, amygdala removal by aspiration causes indirect damage to the neighboring cortical fields by interrupting fiber pathways near the amygdala. Thus, the most parsimonious explanation for finding (3) is that aspiration lesions of the amygdala produced a combination of direct and indirect damage to the rhinal cortex and area TE, rostrally, which, together with the direct damage to portions of the rhinal cortex, caudally, caused the most severe impairments in visual object recognition. Finally, although another region, namely the parahippocampal cortex (areas TF and TH [von Bonin and Bailey, 1947]), has been designated by some investigators (Squire and Zola-Morgan, 1991) as part of the “medial temporal lobe memory system,” experimental evidence shows that this region is unlikely to contribute to either visual or tactual recognition. Removal of the parahippocampal cortex alone yields no impairment on trial-unique visual DNMS (Ramus, Zola-Morgan, and Squire, 1994), and removal of the parahippocampal cortex together with the hippocampus has no effect on tactual DNMS (Murray and Mishkin, 1984).

Object association memory

The central nervous system not only supports recognition of objects, it also can “map” or “associate” objects with other objects or information from other modalities. Recent evidence indicates that many of the same areas that underlie object recognition also contribute to the obligate neural network for object association memory.

An early indication that the ventromedial temporal cortex, namely the entorhinal and perirhinal cortex, might be important for the long-term memory of object associations came from a study in which monkeys were required to learn visual stimulus–stimulus associations, or paired associates (Murray et al., 1993). Trials took the form “If sample *A*, then choose *X* but not *Y* on the choice test; and if sample *B*, then choose *Y* but not *X*.” Monkeys were trained preoperatively on a set of 10 paired associates. Combined removals (by aspiration) of

the amygdala and the hippocampus, which included some of the underlying entorhinal and perirhinal cortex, had a profound effect on both the retention of preoperatively learned paired associates and on the rate of learning of new ones of the same type (Murray, Gaffan, and Mishkin, 1993). By contrast, removals of the amygdala plus the subjacent cortex had a much milder effect on retention, and removal of the hippocampus plus the subjacent cortex had virtually no effect on retention. Furthermore, neither the amygdala nor the hippocampal removal significantly disrupted the learning of new visual paired associates (figure 52.3). These data argue strongly against the idea that the hippocampus is critical for associative memory and for the consolidation of long-term memory about objects. Removals of the rhinal cortex (figure 52.3) cause impairments in new learning comparable to those caused by aspiration lesions of the amygdala plus the hippocampus. Thus, it appears that paired-associate learning, like recognition memory, depends on the entorhinal and perirhinal cortex, and not on the amygdala and the hippocampus, either separately or together (see also Buckley and Gaffan, 1998).

Another recent finding implicates the rhinal cortex in associative mechanisms even more directly. In 1991, Sakai and Miyashita reported “pair-coding” neurons in the inferior temporal cortex of monkeys trained on a paired-associate learning task. These cells showed responses of similar magnitude to separate presentations of certain paired associates but not to other stimuli or other pairs. The probability of this phenomenon occurring by chance is extremely low, so this kind of activity likely reflects information storage. Higuchi and Miyashita (1996) studied the effect of rhinal cortex ablation on pair coding in the following way. Monkeys with transection of the anterior commissure were trained on several pairs of visual stimulus–stimulus associations. After the monkeys had learned a set of stimulus–stimulus associations, the activity of cells in the inferior temporal cortex (the portion lateral to the rhinal cortex) was recorded, and, as expected based on the original study by Sakai and Miyashita (1991), pair-coding neurons were found. The monkeys then received a unilateral excitotoxic lesion of the rhinal cortex and were retrained on the original stimulus–stimulus associations and on a new set of associations as well. Finally, single units were recorded in the same region as for the prelesion control. Although neurons responded selectively to the visual stimuli in both the preoperatively and postoperatively learned sets, there was no evidence of pair coding for either set. Thus, consistent with the evidence from ablation studies, it appears that the rhinal cortex is critical for the emergence and maintenance of the mechanisms that underlie the learning and retention of visual stimulus–stimulus as-

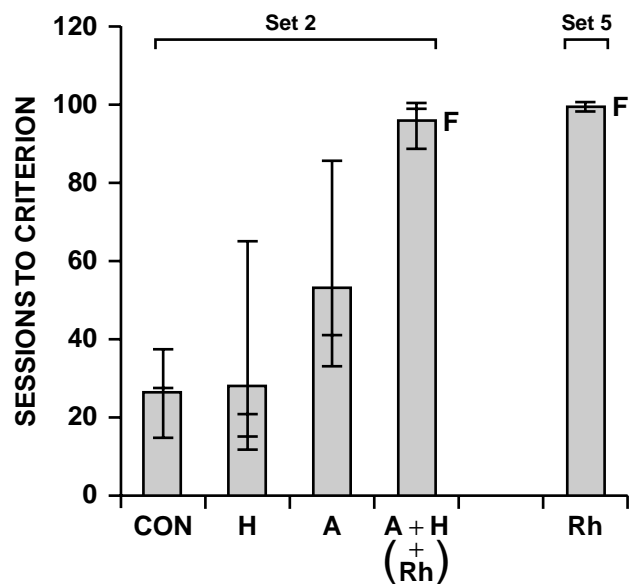

FIGURE 52.3 Postoperative learning of a set of 10 visual paired associates (Murray, Gaffan, and Mishkin, 1993). The height of the bar indicates group mean sessions to learn. Vertical lines indicate the range of scores in each group, and small horizontal hatch marks denote scores of individual monkeys. Note that the monkeys with removal of the rhinal cortex were unable to attain criterion within the training limit of 100 sessions, as were two of the three monkeys with combined removals of the amygdala and the hippocampus that included some of the underlying rhinal cortex. *Abbreviations:* CON, unoperated control monkeys ($N = 3$); H, monkeys ($N = 4$) with aspiration removals of the hippocampal formation plus subjacent cortex; A, monkeys ($N = 3$) with aspiration removals of the amygdala plus subjacent cortex; A + H (+ Rh), monkeys ($N = 3$) with combined aspiration removals of the amygdala and hippocampus that included the subjacent cortex; Rh, monkeys ($N = 2$) with aspiration removals of the rhinal cortex. These animals had served as controls in the main part of the experiment (set 2); set 2, first set of visual paired associates that was learned entirely postoperatively; set 5, fifth set of paired associates; this was the first set learned entirely postoperatively for the group with rhinal cortex lesions. F, failed to attain criterion in the training limit of 100 sessions.

sociations. Higuchi and Miyashita (1996) suggested that the neurons projecting from the rhinal cortex “back” to visual sensory area TE were the critical element of the associative mechanism that had been disrupted.

Because the perirhinal cortex, in particular, is in receipt of sensory inputs from several higher-order modality-specific cortical fields (Suzuki and Amaral, 1994), it is a candidate region for associating together the different sensory qualities of individual objects (figure 52.4). Although an earlier study had suggested that the amygdala was responsible for this type of cross-modal association (Murray and Mishkin, 1985; Murray, 1990), preliminary evidence suggests that the rhinal cortex, rather than the amygdala, is the critical substrate (Goulet and Murray,

FIGURE 52.4 Schematic diagram showing sources of cortical afferent inputs to the rhinal (i.e., perirhinal and entorhinal) cortex. Note that this region receives sensory inputs from both

modality-specific cortical fields (e.g., areas TE and TEO) as well as from polymodal regions (e.g., orbitofrontal cortex). (Adapted from Suzuki, 1996.)

1995). This picture emerges from a study in which monkeys were required to perform a cross-modal DNMS task administered with tactual sample objects (i.e., sample objects presented in the dark) and visual choices (i.e., sample and other objects presented for choice in the light; the choice was known to be guided by vision because the first object touched was scored as the monkey's response). Monkeys were trained to perform this cross-modal tactual-to-visual version of a DNMS task with a fixed set of 40 objects that differed widely in size, shape, texture, and compressibility. As shown in figure 52.5, removal of the anterior portion of the rhinal cortex (the portion underlying the amygdala) but not selective lesions of the amygdala made with the excitotoxin ibotenic acid consistently produced impairments on this task (Goulet and Murray, 1995; Malkova and Murray, 1996). Similarly, removal of the rhinal cortex yields a deficit on a cross-modal task in which the flavor of a food item (including both olfactory and gustatory cues) served to indicate which one of two visual objects should

be chosen (Parker and Gaffan, 1998a), and, in yet another study, removal of the amygdala plus an underlying portion of the rhinal cortex was found to yield an impairment on a task in which auditory cues served to instruct visual choices (Murray and Gaffan, 1994). Thus, in contrast with the earlier idea that the amygdala might mediate cross-modal stimulus-stimulus associations, it appears that this function can be identified as belonging instead to the rhinal cortex. As was the case for another type of object-based associative memory, namely visual paired associates, the hippocampus is not necessary for retention of cross-modal tactual-visual associations (Murray and Mishkin, 1985; Goulet and Murray, unpublished data, 1995).

Taken together, these studies strongly suggest that the rhinal cortex plays a central role in stimulus-stimulus association. Although the rhinal cortex is critical for the formation of new memories involving objects, it is not necessarily the site of storage of those memories. Current models of information storage suggest that stimulus

FIGURE 52.5 Postoperative relearning of tactual-to-visual cross-modal DNMS tasks (Goulet and Murray, 1995). These scores were obtained after an initial postoperative assessment on the same cross-modal task and after retraining on both intramodal versions (visual and tactual) of DNMS tasks. Filled circles show the scores of individual monkeys. Abbreviations: CON, unoperated control monkeys; A, monkeys with excitotoxic lesions of the amygdala; ANT Rh, monkeys with removals of the anterior portion of the rhinal cortex; F, failed to attain criterion in the training limit of 500 trials; numerals indicate the percent correct responses over final 100 trials.

representations are distributed widely throughout the neocortex, and it has been suggested that the projections from the entorhinal and perirhinal cortex back to modality-specific neocortical fields may provide a mechanism enabling this distributed long-term storage. Instead, the mnemonic contribution of the rhinal cortex may be characterized best as one of object identification, part of the process through which the visual, tactual, gustatory, olfactory, auditory, and perhaps motion properties of individual objects, as appropriate, are linked together, and through which environmental stimuli are invested with meaning. The rhinal cortex thus can be viewed as the kernel of a system for storing knowledge about objects, analogous to the semantic memory system in humans (Murray, 1996; Parker and Gaffan, 1998b; Murray, Malkova, and Goulet, 1998).

Is the medial temporal lobe a functionally homogeneous neural network?

As indicated previously, the prevailing view of medial temporal lobe function dictates that the hippocampus, the entorhinal cortex, the perirhinal cortex, and the parahippocampal cortex function collectively in memory. These structures are proposed to operate together as a single functional system supporting declarative mem-

ory (Squire and Zola-Morgan, 1991; Zola-Morgan, Squire, and Ramus, 1994). However, taken to its extreme, which holds that all parts of the medial temporal lobe contribute equally to all of its information-processing functions, this notion contradicts one of the most fundamental principles in biology: the relationship between structure and function. In addition, there are several findings in nonhuman primates that provide clear evidence that different parts of the medial temporal lobe subserve different functions. For example, there are several tests of object memory that are disrupted severely by damage to the rhinal cortex yet are unaffected by damage to the hippocampus. Many of these findings, summarized in table 52.1, have been outlined in earlier sections of this chapter. However, there are several additional findings that are worthy of mention. For example, Gaffan (1994a) has reported that lesions of the perirhinal cortex produce severe impairments on DNMS tasks with scenes but fail to affect spatial reversal learning; conversely, fornix transection disrupts spatial reversal learning but produces only mild effects on a DNMS task (table 52.1). Furthermore, hippocampal lesions yield a temporally limited effect on retrograde memory, disrupting the storage of recently but not remotely learned object discrimination problems (Zola-Morgan and Squire, 1990). By contrast, rhinal cortex removals yield a temporally extensive effect (Thornton, Rothblat, and Murray, 1997), one extending much longer before surgery (at least 16 weeks) than that reported to follow hippocampal removal (8 weeks). Finally, Meunier, Hadfield, and colleagues (1996) found, paradoxically, that ablations of the rhinal cortex, when combined with removal of the hippocampus plus the subjacent parahippocampal cortex (areas TF/TH), yield a recognition deficit that is *less* severe than that which follows rhinal cortex ablation alone. Possible reasons for this outcome are provided elsewhere (Meunier, Hadfield, et al., 1996). Regardless, this finding directly refutes the idea that the medial temporal lobe structures are working together as a single functional unit. Instead, it seems that these structures may interact competitively in information processing (for examples in rodents, see Gallagher and Holland, 1992; McDonald and White, 1995; Matthews and Best, 1995; Bussey et al., 1998).

Neuropsychological studies carried out in rodents have identified dissociations of function among medial temporal lobe structures that parallel those just described in monkeys. Thus, visual recognition is affected little by amygdala plus hippocampal damage in rats (Mumby, Wood, and Pinel, 1992) but is affected greatly by damage to the rhinal cortex (Mumby and Pinel, 1994). Consistent with the foregoing, rhinal cortex damage also has marked effects on olfactory recognition

TABLE 52.1

**Hippocampal system* is defined as the hippocampal formation (hippocampus proper, dentate gyrus, subicular complex) plus fornix.

(Otto and Eichenbaum, 1992). Furthermore, stimulus–stimulus paired associates—in this case, olfactory paired associates—are disrupted by rhinal cortex damage but not by hippocampal damage (Bunsey and Eichenbaum, 1993; Eichenbaum and Bunsey, 1995). Indeed, selective hippocampal damage produces a facilitation in performance on this task. Although these latter studies often differ from those used in monkeys in the sensory modality examined and in the details of the test procedures, they lend general support to the idea that there are multiple functional subdivisions within the medial temporal lobe. In noting the independent contributions of the medial temporal lobe structures to memory, I do not mean to imply that these closely interconnected structures operate in complete isolation from each other, as different “memory systems.” To the contrary, the structures appear to work together in mediating information storage. The next section addresses additional functional specializations of medial temporal lobe structures and considers the interactions among these structures.

Specializations within the medial temporal lobe

If the amygdala, the hippocampus, and the rhinal cortex are making independent contributions to memory, as the data suggest, how are we to apprehend their respective contributions?

LINKING OBJECTS WITH AFFECTIVE VALENCES, PLACES, AND EVENTS Although there is scant evidence available from the study of nonhuman primates, a wealth of data from rodents suggests that the amygdala is critical for eliciting the appropriate emotions in response to en-

vironmental stimuli (see chapter 74 of this volume) and for associating the values of particular reinforcers with stimuli (Cador, Robbins, and Everitt, 1989; Hiroi and White, 1991; Hatfield et al., 1996). Consistent with this idea, selective excitotoxic amygdala damage in monkeys disrupts the normal pattern of emotional responses to objects (Meunier, Bachevalier, et al., 1996) and also disrupts the ability of monkeys to associate the values of particular reinforcers with objects (Malkova, Gaffan, and Murray, 1997).

In addition to being endowed with affective qualities, objects can be embedded in the context of places and events. Putting aside, for the sake of discussion, the commonly held view that the hippocampus functions primarily in spatial memory and spatial navigation generally (for review, see O’Keefe and Nadel, 1978; Eichenbaum, Otto, and Cohen, 1994), some evidence suggests that the hippocampus is needed specifically for learning how to move to particular locations demarcated by objects in the environment. Removal of the perirhinal cortex or of the rhinal cortex does not disrupt place reversal learning (Gaffan, 1994a; Murray, Baxter, and Gaffan, 1998), which is not dependent on the identification of objects in the environment. By contrast, transection of the fornix (Gaffan, 1994a) and aspiration removal of the hippocampus plus the subjacent parahippocampal cortex (Jones and Mishkin, 1972) do disrupt this “nonobject” kind of spatial learning. On another type of spatial memory task, one that requires monkeys to learn about locations within complex two-dimensional (2-D) scenes, lesions of either the rhinal cortex or the hippocampus disrupt the rate at which monkeys learn (Murray, Baxter, and Gaffan, 1998) (see figure 52.6). In the nonobject

FIGURE 52.6 Postoperative learning of spatial scenes (Murray, Baxter, and Gaffan, 1998). The height of the bars shows the group mean errors to criterion averaged across 3 sets consisting of 8 scenes each. Filled circles show the scores of individual monkeys. *Abbreviations:* CON, unoperated control monkeys; Rh, monkeys with removals of the rhinal cortex; PHG, monkeys with removals of the parahippocampal cortex (areas TF and TH); H, monkeys with excitotoxic lesions of the hippocampus. Groups Rh and H are significantly impaired.

spatial task, identical gray plaques typically mark the relevant locations, and information concerning object identification is irrelevant. In the “object-based” spatial task, the relevant locations are presumably identified by their relative distance from particular objects, which also comprise part of the scene. It is tempting to speculate on this basis that the rhinal cortex is necessary for spatial memory only to the extent that “object” processing is involved in that spatial memory. Thus, in tasks such as place reversal learning, in which a “place” is specified by an egocentric frame of reference, the rhinal cortex likely would be unnecessary. In tasks such as spatial scene learning, in which reaching or navigation to a “place” is achieved relative to a particular object or set of objects, the rhinal cortex likely would be critical.

As for event memory, theories of hippocampal function predict that this region might be important for event memory as well as spatial memory. Episodic memory is a term meant to capsulize the information concerning “what,” “where,” and “when” of particular events. (For present purposes, “event” memory and “episodic” memory are used interchangeably, but it should be noted that not all investigators agree with this view.) Humans with damage to structures in the medial temporal lobe, including patients with damage largely restricted to the hippocampal formation, have impairments in event memory; the deficit is considered the core feature of the amnesic syndrome. Thus, hippocampal damage is be-

lieved to produce an impairment in event memory, but this represents only a subset of the broader disruption of declarative memories more generally (e.g., Hamann and Squire, 1995). Gaffan (1994b) has proposed that the learning of spatial scenes constitutes an analog of episodic memory in monkeys.

In short, it appears that the rhinal cortex is critical for knowledge about objects, the hippocampus for knowledge about places and events, and the amygdala for linking object, event, or place information with affective valence. Thus, the medial temporal lobe system might be organized in a hierarchical fashion, with the rhinal cortex providing an initial stage of processing involving object recognition, association, and identification. In later stages, already processed information about objects would be linked with events or affective valences by the hippocampus and amygdala, respectively. If so, we might expect that, to the extent that the later stages of processing require knowledge about objects, damage to the rhinal cortex would disrupt storage of information linking objects with events and affective valence.

There presently are few direct tests of this model. As we already have seen, storage of “fact” information about objects is severely disrupted by damage to the rhinal cortex (Murray, Gaffan, and Mishkin, 1993; Goulet and Murray, 1995; Parker and Gaffan, 1998a) yet appears to proceed normally in the absence of the hippocampus and the amygdala (Murray, Gaffan, and Mishkin, 1993; Murray and Mishkin, 1985; Goulet and Murray, 1995). Object recognition likewise depends on the rhinal cortex (Meunier et al., 1993; Eacott, Gaffan, and Murray, 1994) rather than on the amygdala and the hippocampus (Murray and Mishkin, 1998; cf. Alvarez, Zola-Morgan, and Squire, 1995). In support of the idea that later stages of processing are dependent on earlier ones, Gaffan and Parker (1996) have found that disconnection of the perirhinal cortex from the fornix disrupts learning of an “object-in-place” task, in which monkeys are required to learn object discriminations embedded in complex 2-D scenes. It already has been shown that the fornix provides an advantage in just this type of learning. Thus, the finding indicates that the hippocampal system is indeed dependent on inputs from the perirhinal cortex for performance on this task.

In addition to the findings from monkeys, some evidence from clinical studies also is consistent with the model outlined. Indeed, others (Tulving and Markowitsch, 1998; Mishkin et al., 1997) have presented similar models to the one proposed here, based in part on findings from amnesic patients. Aggleton and Shaw (1996) have reported that, among amnesic patients, those with damage restricted to the hippocampal/fornix system

appear to have minimal recognition deficits, whereas those with damage outside these regions, or in addition to these regions, have greater recognition impairments. In addition, Vargha-Khadem and colleagues (1997) found that patients who had sustained hippocampal damage (with sparing of most of the surrounding cortex) early in life were able to acquire a large amount of factual information and general knowledge about the world, despite their profound deficits in event memory. In agreement with the findings of Aggleton and Shaw, preliminary evidence suggests that these same patients are quite good at stimulus recognition (Mishkin et al., 1997). Moreover, semantic knowledge has been reported to be disrupted by damage to the ventromedial temporal cortex (Hodges et al., 1992; Kapur et al., 1994). Thus, some clinical data support the view that the rhinal and neighboring temporal cortex subserve "fact" memory, object-based information processing, and semantic knowledge, whereas the hippocampus underlies episodic or event memory. This view is countered by the findings of Squire and colleagues, who report that amnesic patients of mixed etiology have deficits in fact memory that are commensurate with their deficits in event memory (Hamann and Squire, 1995) and that amnesic patients with restricted damage to the hippocampus are significantly impaired in recognition (Reed and Squire, 1997). Additional studies need to be conducted before we can draw firm conclusions regarding the proposed hierarchical organization of memory.

ACKNOWLEDGMENTS The author thanks M. G. Baxter, T. J. Bussey, E. Tulving, and S. P. Wise, who kindly provided valuable comments on an earlier version of the chapter. This work is supported by the NIMH-IRP.

53 The Medial Temporal Lobe, the Hippocampus, and the Memory Systems of the Brain

LARRY R. SQUIRE AND BARBARA J. KNOWLTON

ABSTRACT This chapter focuses on the memory systems of the brain, a continuing major theme in behavioral and cognitive neuroscience. One major topic is conscious declarative memory, which depends on the medial temporal lobe and its interaction with the neocortex. Another major topic is retrograde amnesia. The facts about retrograde amnesia provide the key evidence for a lengthy process of reorganization and stabilization within declarative memory that begins after learning has been completed. A related topic concerns how the anatomical components of the medial temporal lobe, including the hippocampus itself, might contribute differently to declarative memory. Another topic centers on the distinction between remembering and knowing. This distinction, which concerns two forms of declarative memory, is of interest because it provides one of the best methods for assessing episodic and semantic memory function in humans. Finally, new information is available about several forms of nondeclarative memory, including the phenomenon of priming, skill and habit learning, artificial grammar learning, category learning, and classical conditioning. New lesion studies and functional neuroimaging studies are illuminating the nature and organization of these forms of memory.

Declarative versus nondeclarative memory

The distinction between declarative (explicit) and nondeclarative (implicit) memory continues as a major theme in behavioral and cognitive neuroscience. This distinction is based on converging evidence from studies of experimental animals, neurological patients, and normal individuals (Schacter and Tulving, 1994; Squire and Zola, 1996). Declarative memory refers to memories for facts and events that are recollected consciously. This type of memory depends on the integrity of medial temporal lobe structures, including the hippocampus, as well as midline diencephalic nuclei. Nondeclarative memory is expressed through performance without any requirement

for conscious memory content. Nondeclarative memory is independent of the medial temporal lobe and diencephalic structures that support declarative memory. Nondeclarative memory is not a single entity but rather describes a collection of abilities: memory for skills and habits, simple forms of conditioning, and priming.

Describing the properties of declarative and nondeclarative memory independently of their neuroanatomy is an important goal. Declarative memory is well suited for storing information about single events. The knowledge is flexible and applied readily to novel situations. In general, nondeclarative memory is inflexible and bound to the learning situation. Unlike declarative memories, nondeclarative memories cannot be accessed readily by response systems that did not participate in the original learning (Eichenbaum, Mathews, and Cohen, 1989; Reber, Knowlton, and Squire, 1996; Saunders and Weiskrantz, 1989).

Retrograde amnesia

The brain system that supports declarative memory has only a temporary role in the formation of long-term memory. Retrograde amnesia, the loss of memories that were acquired before the onset of amnesia, usually is graded temporally so that recent memories are more impaired than remote memories (Ribot, 1881). Retrograde amnesia sometimes can be ungraded and extensive, as in conditions such as encephalitis and head trauma, when damage typically occurs beyond the brain system that supports declarative memory (e.g., Damasio et al., 1985; Cermak and O'Connor, 1983; Reed and Squire, 1998). Nevertheless, in patients with restricted damage to the CA1 zone of the hippocampus proper, such as patient R.B. (Zola-Morgan, Squire, and Amaral, 1986) and patient G.D. (Rempel-Clower et al., 1996), retrograde amnesia is brief, perhaps covering 1 or 2 years at most. Other patients with more complete damage to the hippocampal formation also have temporally limited

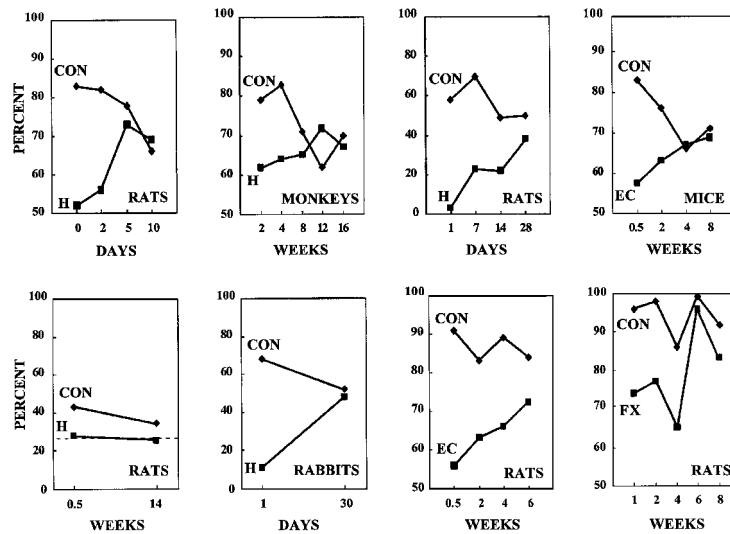

FIGURE 53.1 The panels show all the studies through 1998 in which an equivalent amount of training was given at each of two or more times before hippocampal formation damage, and retention was assessed shortly after surgery. The eight studies involve eight different tasks and four species. In each case, the data show the performance of control (CON) and operated animals (H = hippocampus, EC = entorhinal cortex, FX = fornix) as a function of the interval between training and surgery. Control animals typically exhibited forgetting as the interval between training and surgery increased. In seven of the eight studies, operated animals exhibited temporally graded retrograde amnesia. They were impaired at retaining material they had learned recently, but they retained re-

motely learned material as well as control animals. In addition, the operated animals typically retained remotely learned material better than recently learned material. In the lower left panel, both groups of operated animals performed at chance levels (dotted line), which could have obscured a temporal gradient of amnesia if one were present. From left to right, beginning on the top row, the studies are by Winocur (1990); Zola-Morgan and Squire (1990); Kim and Fanselow (1992); Cho and associates (1993); Bolhuis and associates (1994); Kim and colleagues (1995); Cho and Kesner (1996); and Wiig and coworkers (1996). (From Milner, Squire, and Kandel, 1998. Reprinted with permission of Cell Press.)

retrograde amnesia (Reed and Squire, 1998), but graded loss of memory can extend back a decade or more (Rempel-Clower et al., 1996).

Because the study of human retrograde amnesia is based almost entirely on findings from retrospective tests, the clearest evidence about retrograde amnesia gradients comes from studies using experimental animals, where the delay between initial learning and a lesion can be manipulated directly (figure 53.1). These studies make three important points: (1) temporal gradients of retrograde amnesia can occur within long-term memory (i.e., retrograde amnesia does not reflect simply the vulnerability of a short-term memory that has not yet been converted into a long-term memory); (2) after a lesion, remote memory can be retained better than recent memory; and (3) lesions can spare weak memories while disrupting strong ones. To illustrate these three points, consider the case of rabbits given trace eyeblink conditioning. Trace conditioning is a variant of classical conditioning in which the conditioned stimulus (CS), such as a tone, is presented and terminated, and then a short interval is imposed before the presentation of the unconditioned stimulus (US). In normal rabbits, forgetting occurs gradually after training; thus, retention of the

conditioned response is much poorer 30 days after training than after only 1 day. Nevertheless, complete aspiration of the hippocampus 1 day after training abolished the strong 1-day-old memory, whereas the same lesion made 30 days after training had no effect on the weaker, 30-day-old memory (Kim, Clark, and Thompson, 1995; figure 53.1).

The results from experimental animals provide evidence for a gradual process of reorganization and stabilization in the neocortex whereby long-term memory eventually becomes independent of the medial temporal lobe. The medial temporal lobe is the target of highly processed information originating from a variety of cortical regions, and it returns projections to these same cortical regions. The hippocampal formation may direct a process of reorganization in the neocortex by gradually binding together the multiple, geographically separate cortical regions that together store memory for a whole event (Alvarez and Squire, 1994; Squire and Alvarez, 1995; McClelland, McNaughton, and O'Reilly, 1995). The lengthy time period required by this process suggests that morphological growth and change may be required at the synapses within the corticocortical projections that comprise a representation.

There is precedent for gradual changes in neuronal morphology occurring as the result of behavioral experience. Specifically, gradual morphological changes can occur in visual cortical neurons as the result of a small retinal lesion. These changes serve to reduce the size of the visual scotoma and are likely driven by continuing sensory input (Darian-Smith and Gilbert, 1994). To explain why this long process occurs in the organization of long-term memory, McClelland and associates (1995) suggested on computational grounds that the hippocampal system itself can learn specific instances rapidly but that information can be incorporated into the neocortex only gradually. The gradual incorporation of information into neocortex minimizes disruption of existing knowledge structures. Much more needs to be learned about this gradual process. Interestingly, measured against life span, a 30-day gradient of retrograde amnesia in a mouse or rat is equivalent to a gradient of a few years in a human. Whether such a comparison is meaningful must await parametric studies of retrograde amnesia in experimental animals and the identification of which task factors can influence the severity and extent of retrograde amnesia.

Components of the medial temporal lobe memory system

Studies with monkeys and humans have identified the brain structures within the medial temporal lobe that are important for declarative memory. These structures are the hippocampus, the entorhinal cortex, the parahippocampal cortex, and the perirhinal cortex (figure 53.2). The amygdala, although critical for aspects of emotional learning (Davis, 1994; LeDoux, 1996) and for the enhancement of declarative memory by emotion (Adolphs et al., 1997), is not critical for declarative memory itself (Zola-Morgan, Squire, and Amaral, 1989).

The question whether these medial temporal lobe structures play different roles in declarative memory follows naturally from the fact that anatomical connections from different parts of the neocortex enter the medial temporal lobe at different points (Suzuki and Amaral, 1994a, b). For example, the visual association cortex, including area TE, projects more strongly to the perirhinal cortex than to the parahippocampal cortex, whereas the parietal cortex projects to the parahippocampal cortex but not to the perirhinal cortex.

The evidence from monkeys and humans at first might seem to count against the idea that the different structures of the medial temporal lobe have distinct functions. The data are that the severity of memory impairment increases as more components of the medial

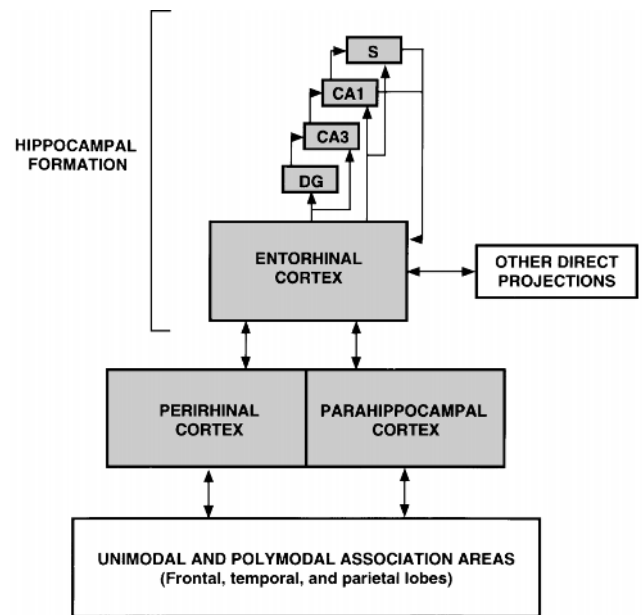

FIGURE 53.2 Schematic view of the medial temporal lobe memory system. The entorhinal cortex is a major source of projections to the hippocampal region (which includes the dentate gyrus, the cell fields of the hippocampus proper, and the subicular complex). Nearly two thirds of the cortical input to the entorhinal cortex originate in the adjacent perirhinal and parahippocampal cortices, which in turn receive projections from unimodal and polymodal areas in the frontal, temporal, and parietal lobes. The entorhinal cortex also receives other direct inputs from the orbital frontal cortex, the insular cortex, the cingulate cortex, and the superior temporal gyrus. All these projections are reciprocal. (From Squire and Zola, 1996. Copyright 1996 National Academy of Sciences, U.S.A.)

temporal lobe are damaged (Rempel-Clower et al., 1996; Zola-Morgan, Squire, and Ramus, 1994). However, these findings are compatible with the idea that different components of the medial temporal lobe contribute to memory in different ways. As damage increases, fewer strategies may be available for storing memory, resulting in more severe memory impairment.

Direct comparisons of the separate effects of perirhinal and parahippocampal lesions suggest that these structures may play distinct roles, as the neuroanatomical findings first suggested. Visual recognition memory appears to be more dependent on the perirhinal cortex than the parahippocampal cortex (Squire and Zola, 1996), whereas spatial memory appears to be more dependent on the parahippocampal cortex than the perirhinal cortex (Malkova and Mishkin, 1997; Parkinson, Murray, and Mishkin, 1988; Teng, Squire, and Zola, 1997).

There also has been interest in which, if any, memory functions can be identified that are specific for the hippocampus. Anatomically, the hippocampus lies at the end of the medial temporal lobe system and is a recipient of convergent projections from each of the

structures that precedes it in the hierarchy (figure 53.2). This arrangement has suggested to some that the hippocampus has a special role in memory tasks that depend especially on relating or combining information from multiple sources, such as spatial information or information about specific events, as opposed to factual knowledge (Mishkin et al., 1997; Nadel, 1991; Eichenbaum, Otto, and Cohen, 1994). These possibilities are active topics of investigation. Three observations seem warranted at this point.

First, it is clear that animals with neurotoxic damage limited to the hippocampus are impaired at nonspatial memory tasks (Bunsey and Eichenbaum, 1996). Spatial tasks are simply a good example of the large category of declarative memory abilities that are impaired after hippocampal damage (Squire, 1992). Second, in monkeys and humans, damage limited to the hippocampal region (hippocampus, dentate gyrus, and subicular complex) impairs simple tasks of recognition memory (Reed and Squire, 1997; Zola et al., 1998). For example, monkeys with circumscribed, radiofrequency lesions of the hippocampal region were impaired in the visual paired-comparison task (Zola et al., 1998). This task measures familiarity for recent stimuli by taking advantage of the natural (untrained) tendency that monkeys have to look longer at novel pictures than familiar pictures. Third, formal tests suggest that amnesic patients with hippocampal region damage have difficulty learning new facts just as they have difficulty learning about new events (Hamann and Squire, 1995; also see Squire and Zola, 1998).

These considerations suggest that the hippocampal region is important for both spatial and nonspatial memory, for both recognition memory and recall, and for both fact and event memory. This is, in fact, the impression that one gains through study of amnesic patients like R.B. and G.D., who had bilateral damage limited to the CA1 region of the hippocampus. If the hippocampus has some unique function that can be detected in behavioral measures, then there should be some memory task that G.D. and R.B. would have performed as poorly as patients with CA1 damage plus damage to other medial temporal lobe structures (e.g., the well-studied amnesic patient H.M. [Scoville and Milner, 1957]). However, G.D. and R.B. appeared simply to be less severely affected than patients like H.M. One possibility is that the hippocampus makes a unique contribution to declarative memory, but that this contribution will become clear only when the intrinsic circuitry of the hippocampus is better understood computationally. Another possibility is that the hippocampus, as the result of its placement at the end of the processing hierarchy of the medial temporal lobe (figure 53.2), combines and ex-

tends the functions of the structures that are positioned earlier in the hierarchy. In this view, the hippocampus supports and extends the operations of the structures that send projections to it, and studies of lesions and behavior would not reveal deficits unique to the hippocampus that could not also be observed by damaging the perirhinal cortex, the parahippocampal cortex, or the entorhinal cortex.

The distinction between remembering and knowing

When an item evokes a conscious recollection that includes specific information about the item and the context in which the item was learned, a subject is said to “remember” (R). When a subject is confident an item is familiar and was seen before, but is unable to remember anything about the item in its original learning context, the subject is said to experience “knowing” (K) (Tulving, 1985). In some respects, the distinction between remembering and knowing is similar to the distinction between declarative and non-declarative memory, and R and K responses can be dissociated in a number of ways that are reminiscent of that distinction (Gardiner and Parkin, 1990). However, recent work shows that both R and K responses are impaired in amnesia (Knowlton and Squire, 1995; figure 53.3; Kroll, Yonelinas, and Knight, 1997). Accordingly, the evidence suggests that remembering and knowing are two different expressions of declarative memory.

In another study, event-related potentials (ERPs) from recently presented items that elicited R responses were similar to ERPs from recently presented items that elicited K responses until 500 ms after each item was presented (Smith, 1993). However, items that were endorsed as having been presented before (i.e., all the items that received either R or K responses) could be distinguished from items that were endorsed as new items beginning approximately 350 ms after item presentation. Smith (1993) suggested that both R and K responses result from a common process of recollection dependent on declarative memory. The distinction between R and K responses then arises from a postrecollective process, when subjects attend to the products of their retrieval efforts.

The nature of this postrecollective component of memory has been described in a number of ways. Tulving (1989) originally described remembering and knowing as measuring episodic and semantic memory, respectively. Items that are “remembered” after a short study-test delay are likely to become merely “known” after a long delay, and this transition has been likened to the transition between episodic and semantic memory (Conway et al., 1997).

FIGURE 53.3 Recognition memory (measured by d' , discriminability) for test items labeled *remember* (R; open bars) or *know* (K; closed bars) by amnesic patients (AMN) and two control groups (CON). The amnesic patients ($n = 13$) were tested 10 minutes after the study phase, and the control groups were

tested 10 minutes ($n = 14$) or 1 week after the study phase ($n = 11$). For amnesic patients, the accuracy of both R responses and K responses were impaired. Brackets show standard errors of the mean. (From Knowlton and Squire, 1995.)

This line of thinking leads to the idea that although remembering and knowing are both forms of declarative memory, they nevertheless can be distinguished in a fundamental way. Whereas both remembering and knowing are dependent on the medial temporal lobe and diencephalic brain structures that support declarative memory, remembering depends additionally on the frontal lobes (Schacter, Harbluk, and McLachlan, 1984; Janowsky, Shimamura, and Squire, 1989). In one study, elderly individuals were impaired in remembering (i.e., making accurate R responses) in proportion to the extent that they exhibited neuropsychological signs of frontal lobe dysfunction (Parkin and Walter, 1992).

One critical component of “remember” judgments seems to be the availability of source memory. Individuals often describe an item as “remembered” because they have a specific memory of the learning context for that item. They remember the source of the item. Source memory is sensitive to frontal lobe damage (Schacter, Harbluk, and McLachlan, 1984; Janowsky, Shimamura, and Squire, 1989), consistent with the idea that remember “judgments” depend on the integrity of the frontal lobes. However, remember judgments are not fully equivalent to source judgments, broadly defined, because even when individuals recognize an item by familiarity (a “know” response), they still are indicating in their endorsement of the item that they believe the items were presented during the study phase. Thus, remem-

bering and knowing both require knowledge that a test item was encountered recently in the study context, but remembering additionally requires that specific information be available about a particular moment in recent time when the item was encountered.

Nondeclarative memory

PRIMING Priming refers to the enhanced ability to identify or produce a stimulus as a result of its recent presentation. The first encounter with an item results in a representation of that item, which then allows it to be processed more efficiently than items that were not encountered recently. Priming is not merely the activation of previously existing representations because priming can occur for novel material, including orthographically illegal nonwords such as KHSF (Keane et al., 1995b; Hamann and Squire, 1997) and for newly associated word pairs (Gabrieli et al., 1997; Poldrack and Cohen, 1997). Some of the best evidence that priming is a distinct form of memory comes from the finding that amnesic patients exhibit intact priming (see Schacter, Chiu, and Ochsner, 1993, for a review).

The dissociation between intact priming and impaired recognition memory in amnesic patients is particularly compelling. One study investigated priming in a patient who is so severely amnesic that he exhibits no detectable declarative memory (Hamann and Squire, 1997). Patient

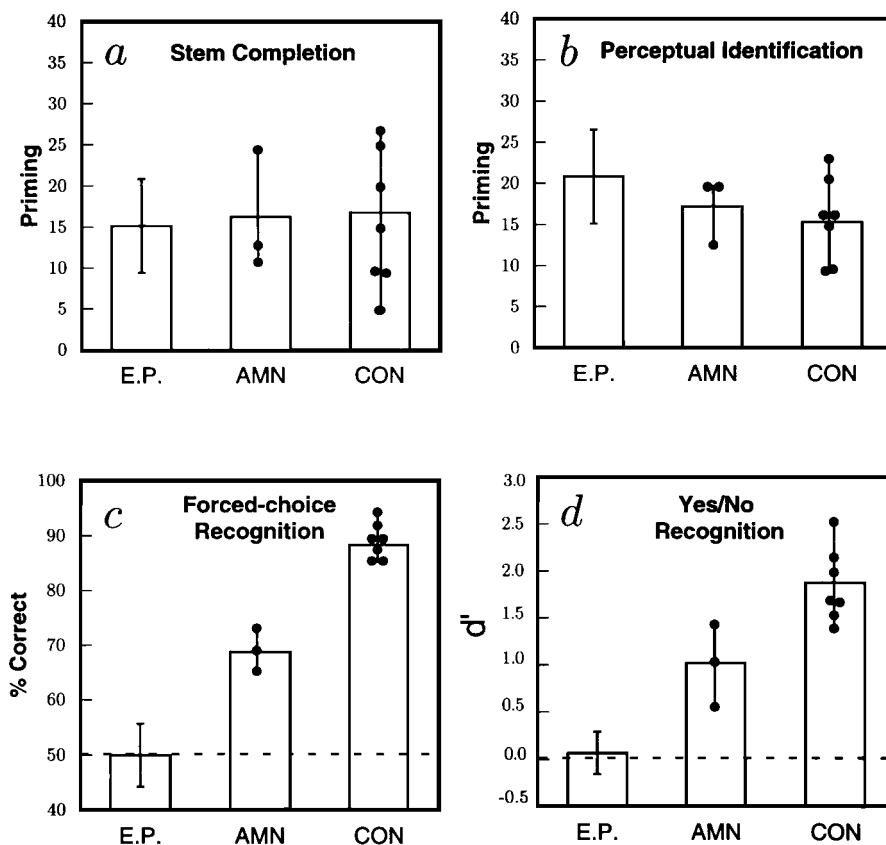

FIGURE 53.4 Performance on four different memory tests after studying 24 simple English words. (A) Stem completion priming. Six priming tests were given to the severely amnesic patient E.P., other less severely affected amnesic patients (AMN, $n = 3$), and normal controls (CON, $n = 7$). Priming scores were calculated as percentage correct for studied items minus percentage correct for nonstudied items. (B) Perceptual identification priming. Twelve tests were given to all participants. Priming scores were calculated as percentage of correct identifications of studied items minus percentage of correct identifications of nonstudied items. (C) Two-alterna-

tive, forced-choice recognition. Percentage correct across six tests for each participant. (D) Yes–no recognition. Discrimination accuracy (d') is shown across six tests for each participant. Percentage correct scores (hits plus correct rejections) were 52%, 65%, and 81% for E.P., AMN patients, and CON participants, respectively. Brackets for E.P. indicate the standard error of the mean; the data points for AMN and CON groups indicate individual participant means across all the tests. Dashed lines indicate chance performance. (From Hamann and Squire, 1997.)

E.P. sustained complete bilateral damage to the medial temporal lobe as the result of herpes simplex encephalitis. Two tests of priming were given—perceptual identification of words and word-stem completion. Two parallel tests of recognition memory for words were also given—two-alternative forced-choice and yes–no recognition. Each test was given 6 to 12 times to obtain a robust measure of performance. The result: E.P. performed entirely normally on the two priming tests but performed at chance on the recognition tests (figure 53.4). These results support the idea that priming depends on brain structures independent of the medial temporal lobe memory system. In addition, the fact that E.P. performed at chance on the recognition tests shows that he was unable to benefit his recognition performance by using the information available to him from priming.

The anatomical locus of perceptual priming appears to be in posterior neocortex. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies have shown that primed items result in less activation in the posterior neocortex than do unprimed items (Schacter and Buckner, 1998). For example, in a word-stem completion task, volunteers showed reduced activation of the right posterior cortex while completing stems of words that had been presented recently, for example, study BRIDE, complete BRI__ (Squire et al., 1992). This decrease in activation likely reflects a decrease in the resources required to process material when it recurs because the material left a trace in the visual pathways after its first presentation.

Two patients with unilateral extrastriate lesions have been identified who performed poorly on visual percep-

tual priming tasks, but who exhibited intact recognition memory for the same stimuli (Gabrieli et al., 1995; Keane et al., 1995a). These patients also exhibited intact nonvisual priming and intact semantic priming. This dissociation of priming and recognition memory provides further support for the idea that these two forms of memory depend on different brain systems. The patients may have achieved normal recognition memory performance by accessing different information than is used to support priming. Whereas perceptual priming depends on the visual features of the stimulus items, recognition memory could draw on phonetic or semantic information that was established in parallel with and independently of information about visual features.

SKILLS AND HABITS The learning of motor, perceptual, and cognitive skills is largely nondeclarative in some circumstances, as evidenced by the fact that amnesic patients can learn some skills at an entirely normal rate. In one study, amnesic patients and control subjects performed a serial reaction-time task (Nissen and Bullemer, 1987) in which they responded successively to a sequence of four illuminated spatial locations. The task was to press one of four keys as rapidly as possible as soon as the location above that key was illuminated. Amnesic patients and normal subjects successfully learned a repeating sequence of locations, as indicated by gradually decreasing reaction times for key presses as the sequence repeated itself. When the sequence was changed, reaction times increased again. Amnesic patients learned the sequence even when they had little or no declarative knowledge of it, as measured by four different tests of declarative knowledge (Reber and Squire, 1994).

In a second study, the distinction between procedural knowledge for the sequence and declarative knowledge for the sequence was established in a different way. Amnesic patients received extended practice on a sequence (1200 trials), and control subjects were given no practice but attempted to memorize the sequence during a brief period of 60 observation trials (Reber and Squire, 1998). The result: control subjects answered questions about the sequence better than the amnesic patients, but the amnesic patients exhibited better nondeclarative knowledge of the sequence than the controls, as measured by their improved reaction times while performing the task.

Neuropsychological studies of skill learning point to the involvement of the neostriatum in many of the tasks. Patients with striatal damage, including patients with Huntington's disease or Parkinson's disease, are impaired at acquiring perceptuomotor skills (see Salmon and Butters, 1995, for a review). Functional neuroimaging also has implicated the neostriatum in the serial reaction time task (Doyon et al., 1996; Grafton, Hazeltine,

and Ivry, 1995; Hazeltine, Grafton, and Ivry, 1997; Rauch et al., 1997).

Habit learning refers to stimulus-response-based associations that are formed gradually and independently of declarative memory for the training episode (Mishkin, Malamut, and Bachevalier, 1984). In experimental animals, there is strong evidence that the neostriatum is essential for habit learning (White, 1997). To study habit learning in humans requires thwarting the tendency to memorize the structure of the task by using declarative memory. For example, in the win-stay radial-arm maze task, rats gradually learn the habit of entering a lit arm across many trials. However, humans could learn to enter a lit arm in a single trial by acquiring the declarative fact "light signals food."

We developed a task in which the probabilistic nature of what was to be learned made a declarative memorization strategy ineffective (Knowlton, Squire, and Gluck, 1994). Information learned on single trials is not nearly as useful as information abstracted across many trials. The task was presented to subjects as a weather prediction game in which a series of cues appear on a computer screen, and the subject must guess on each trial whether the cues predict sunshine or rain (figure 53.5). Subjects receive feedback on every trial, and memorization is minimized by requiring subjects to respond within 5 seconds. Although subjects often report that they are simply guessing, they nevertheless show evidence of learning. They begin the task performing at chance (50% correct), and they end up after 50 trials choosing the most associated outcome approximately 70% of the time.

As is the case with habit learning tasks studied in experimental animals, the medial temporal lobe memory system is not necessary for this type of learning. Amnesic patients were able to learn normally across the first 50 trials of this task (Knowlton, Squire, and Gluck, 1994). Further evidence that the probabilistic classification task is an example of habit learning is provided by the fact that patients with Parkinson's disease exhibited significant impairment on this task. In fact, a double dissociation was found between amnesic patients and Parkinson patients. Amnesic patients learned the task but then could not answer questions about the nature of the task and what they had done. Parkinson patients failed to learn the task but were normal at answering questions about the test episode (Knowlton, Mangels, and Squire, 1996; figure 53.6). These data provide evidence for the existence of a neostriatal habit learning system in humans.

ARTIFICIAL GRAMMAR LEARNING In an artificial grammar learning task, subjects are presented with a

FIGURE 53.5 Appearance of the computer screen at the beginning of the probabilistic classification task. The four cues are shown along with the sun and rain icons. On each trial, one, two, or three of these cues were presented side by side (in 1 of the 14 possible combinations), and individuals predicted whether the outcome would be sunshine or rain by pressing one of two keys. Feedback was provided immediately to signal

a correct or incorrect response. A particular cue was associated with the outcome sunshine either 75%, 57%, 43%, or 25% of the time, and thus either 25%, 43%, 57%, or 75% of the time with the other outcome (rain). For each person in the study, the four cues were randomly assigned one of these probabilities. Testing proceeded for 50 trials. (From Knowlton, Squire, and Gluck, 1994.)

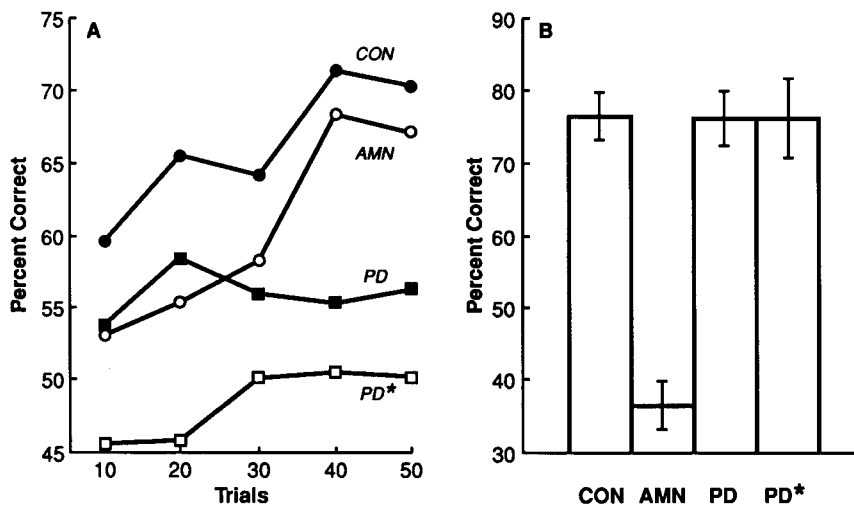

FIGURE 53.6 (A) Performance on the probabilistic classification task by controls (CON, $n = 15$), amnesic patients (AMN, $n = 12$), patients with Parkinson's disease (PD, $n = 20$), and a subgroup of the PD patients with the most severe symptoms (PD*, $n = 10$). None of the groups performed significantly above chance levels (50% correct) on the first block of 10 trials. The controls and amnesic patients gradually learned the cue–outcome associations during 50 trials. The PD patients exhibited no measurable learning across 50 trials. (B) Performance on a declarative memory task that asked about the

testing episode. Both PD and PD* groups exhibited entirely normal declarative memory for facts about the testing episode, despite their poor performance on the classification task itself. In contrast, the amnesic patients exhibited a severe impairment in declarative memory for the testing episode but normal performance on the classification test. Brackets show standard errors of the mean. (Reprinted with permission from Knowlton, Mangels, and Squire, 1996. Copyright 1996 American Association for the Advancement of Science.)

series of letter strings that are formed according to a finite-state rule system like the one in figure 53.7. After viewing these letter strings, subjects are told for the first time that the letter strings were formed according to a set of rules and that their task is to decide for a

new set of letter strings whether each one is formed by the same set of rules. Even though subjects typically report that they are simply guessing, they are able to classify new letter strings as “grammatical” or “non-grammatical” significantly above chance (see Reber,

FIGURE 53.7 Artificial grammar learning. Letter strings are generated from a finite state rule system. Grammatical letter strings are formed by traversing the diagram from the in arrow to the out arrows, adding a letter at each transition from one node to the next. Nongrammatical letter strings are formed by introducing an error into a grammatical letter string. (From Knowlton and Squire, 1994.)

1989, for a review). Interestingly, amnesic patients classify items as grammatical or nongrammatical as well as normal subjects, despite being impaired at recognizing the letter strings that were used during training (Knowlton, Ramus, and Squire, 1992; Knowlton and Squire, 1994; 1996; figure 53.8).

The information that is acquired nondeclaratively in an artificial grammar learning task initially was assumed to be some veridical portion of the actual rule system that was used to form the exemplars. However, grammatical and nongrammatical letter strings differ in other ways besides their adherence to grammatical rules. For example, test letter strings that are grammatical are more likely to be composed of letter bigrams and trigrams (chunks) that appeared frequently in the training exemplars than are nongrammatical letter strings. In this sense, grammatical letter strings are considered to have a higher “chunk strength” than nongrammatical items. It turns out that subjects are likely to endorse as grammatical those test items with high chunk strength, regardless of whether the items follow grammatical rules. This finding demonstrates that the information learned about an artificial grammar includes very simple, concrete associations between features of the training items and the test

items (Knowlton and Squire, 1994; Servan-Schreiber and Anderson, 1990).

It also is true that subjects are able to transfer some knowledge about an artificial grammar to letter strings composed of entirely new letters, and they can even accomplish a change in sensory modality from training to testing (Altmann, Dienes, and Goode, 1995). Thus, it appears that subjects are able to learn some abstract information about the artificial grammar, which then allows them to transfer their knowledge to new test items that differ in surface structure. The question of whether learning on this task is abstract or concrete is orthogonal to the question of whether this learning is declarative or nondeclarative. Amnesic patients and normal subjects appear to exhibit the same sensitivity to chunk strength, and they both transfer to stimuli formed using new letters (Knowlton and Squire, 1996). Thus, both abstract and concrete information can be learned nondeclaratively.

Patients with basal ganglia dysfunction can accomplish artificial grammar learning (Knowlton et al., 1996; Reber and Squire, in press). The fact that much of artificial grammar learning is based on concrete, item-specific information about bigrams and trigrams raises the possibility that this type of learning could resemble priming or perceptual learning. For example, it was shown that subjects trained on an artificial grammar are able to perceive grammatical letter strings at a shorter exposure duration than nongrammatical letter strings, demonstrating that the grammatical letter strings enjoy enhanced perceptual fluency (Buchner, 1994). If so, artificial grammar learning may depend on changes within the neocortex.

CATEGORY LEARNING After exposure to several exemplars of a category, subjects are able to classify new items according to whether they are members of that category. In addition, subjects identify the prototype, or central tendency of the category, as a member of the learned category more readily than the items used during training, even when the prototype itself was not presented during training. Such findings originally were interpreted as showing that subjects abstract a prototype from the training exemplars and use the abstracted prototype to classify new items. However, computational work has shown that superior classification of prototypes also occurs when nothing is stored except the characteristics of individual exemplars (Medin and Schaffer, 1978). The prototype usually is similar to a large number of the training items so that it would be strongly endorsed if subjects were making their judgments by making comparisons between each test item and the exemplars stored in memory.

FIGURE 53.8 The results of three separate studies showing normal performance of amnesic patients (AMN) compared with control subjects (CON) on classification tasks based on ar-

tificial grammars. Brackets show standard error of the mean. (From Knowlton, Ramus, and Squire, 1992, and Knowlton and Squire, 1994.)

The matter of whether category learning depends on abstracting a prototype or whether it is exemplar based is orthogonal to the issue of whether category learning is declarative or nondeclarative. Support for the idea that category learning is nondeclarative comes from the finding that amnesic patients are able to classify items according to a learned category, despite a severe deficit in recognizing the items that were used to train the category (Knowlton and Squire, 1993). The task was similar to one developed by Posner and Keele (1968). Amnesic patients and control subjects were shown a series of dot patterns formed by distorting a randomly generated pattern that was defined arbitrarily as the prototype of the category. Having seen a series of dot patterns, all of which were distortions of an underlying prototype, subjects then were able to discriminate new dot patterns that belonged to the training category from other dot patterns that did not (figure 53.9). Amnesic patients performed the same as control subjects, even though the patients were severely impaired at recognizing which dot patterns had been presented for training. These data demonstrate that category-level knowledge can be acquired nondeclaratively. Moreover, if category-level knowledge is exemplar based, then it is independent of the exemplar-based information used to support recognition memory.

A challenge to the notion that classification and recognition arise from independently acquired sources of knowledge comes from computational work showing how the performance of amnesic patients could depend on a single knowledge base. The key idea is that the function relating exemplar knowledge and classification performance is nonlinear. If a little exemplar knowledge is all that is needed to achieve near-normal classification performance, then amnesic patients could perform nearly

FIGURE 53.9 Examples of the 40 study items and 84 test items used to assess category learning of dot patterns. The study items were all distortions of a prototype dot pattern that was not presented. The test items were new dot patterns, either presentations of the prototype ($n = 4$), low distortions of the prototype ($n = 20$), high distortions of the prototype ($n = 20$), or random dot patterns ($n = 40$). (From Squire and Knowlton, 1995. Copyright 1995 National Academy of Sciences, U.S.A.)

normally on category learning, despite having impaired exemplar knowledge as assessed by recognition memory (Nosofsky and Zaki, 1998).

This possibility has been addressed in two ways. First, amnesic patients and patients with Parkinson's disease demonstrated a double dissociation between classification performance and recognition memory on the probabilistic classification task (figure 53.6). This finding shows that, for this task, knowledge stores appear to be independent. Classification is not simply easier than recognition because the patients with Parkinson's disease actually found classification more difficult than recognition (Knowlton et al., 1996).

Another way to test the independence of classification and recognition is to test the category-learning abilities of a patient who has no detectable declarative memory capacity. If normal category learning occurs in such a patient, then classification performance must be based on nondeclarative knowledge. This set of requirements was met with the severely amnesic patient E.P. (Squire and Knowlton, 1995). After viewing 40 different dot patterns, he classified new dot patterns as well as normal subjects (figure 53.10). Six different tests were given to obtain a robust performance measure. Despite his intact ability to classify new dot patterns, he failed to recognize a single dot pattern as familiar after it had been presented 40 times consecutively. This recognition test also was repeated six different times. It is not clear how to explain these results except to suppose that learning about categories can occur independently of declarative memory.

Category learning, like artificial grammar learning, may resemble priming effects with respect to the importance of perceptual fluency. Categorical dot patterns presented at test are similar to previously viewed patterns and therefore may be processed more rapidly and less effortfully than noncategorical patterns. Accordingly, the prototype of the trained category would benefit the most from perceptual fluency because it should be similar to a larger number of training items than any other individual dot pattern. Similarly, dot patterns that resemble the prototype should benefit more from perceptual fluency than random dot patterns. Neuroimaging data support this idea (Reber, Stark, and Squire, 1998). Volunteers studied 40 dot patterns that were distortions of an underlying prototype and then, while fMRI data were collected, they made yes-no category judgments about new dot patterns. Posterior occipital cortex (areas 17/18) exhibited less activity during processing of the categorical patterns than during processing of noncategorical patterns. This result suggests that category learning and perceptual priming may be based on similar mechanisms. That is, decreased activity in the posterior cortex may occur not only when a stimulus is repeated a second time but also when a stimulus is presented that is similar to one seen earlier.

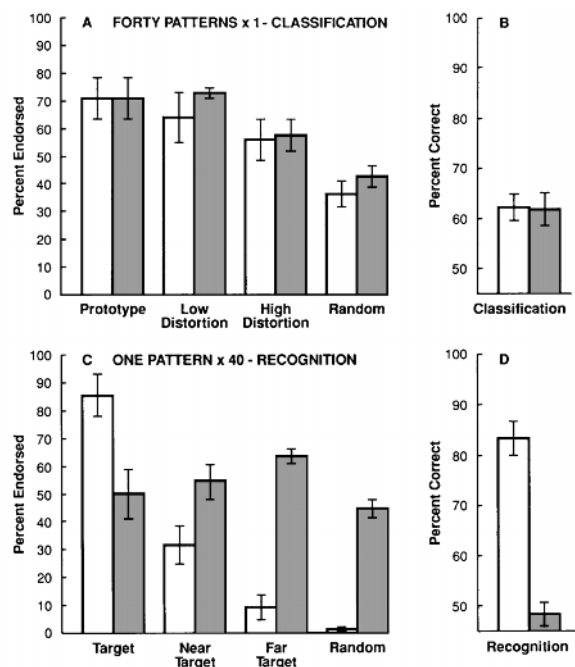

FIGURE 53.10 Performance on parallel tasks of categorization and recognition memory by the severely amnesic patient E.P. and control subjects. All subjects were tested six times on both tests. Brackets show standard errors of the mean. (A) Categorization. Classification of 84 novel dot patterns 5 minutes after studying 40 different training patterns (that were distortions of a prototype dot pattern). Control subjects ($n = 4$, open bars) and E.P. (closed bars) performed similarly, endorsing test items as a function of how closely they resembled the prototype of the training category. There were four types of test items (4 prototypes, 20 low distortions, 20 high distortions, and 40 random dot patterns). (B) Overall percentage correct scores for classification. E.P. performed as well as control subjects at categorization. (C) Recognition. Recognition memory 5 minutes after 40 presentations of the same prototype dot pattern. The recognition test was structured identically to the categorization test (A), and only the instructions differed—that is, recognition instead of classification. Thus, at test there were 4 presentations of the prototype target pattern, 20 near targets, 20 far targets, and 40 random patterns. (D) Overall percentage correct scores for recognition. Correct responses consisted of endorsements of the training pattern (the 4 targets) and rejections of the other 80 patterns. E.P. performed at chance. (From Squire and Knowlton, 1995.)

CLASSICAL CONDITIONING Classical conditioning is an extensively studied example of simple associative learning and, in its simplest form, is a quintessential example of nondeclarative memory. The best studied paradigm, delay conditioning of the eyeblink response (conditioned stimulus = tone; unconditioned stimulus = airpuff to the eye) is reflexive and automatic and depends solely on structures below the forebrain, including the cerebellum and associated brainstem circuitry (Thompson and Krupa, 1994). Amnesic patients also exhibit intact

FIGURE 53.11 A taxonomy of mammalian long-term memory systems. The taxonomy lists the brain structures thought to be especially important for each form of declarative and nondeclarative memory. In addition to its central role in emotional

learning, the amygdala is able to modulate the strength of both declarative and nondeclarative memory. (From Squire and Zola, 1996.)

acquisition and retention of delay eyeblink conditioning (Daum and Ackerman, 1994; Gabrieli et al., 1995).

In trace conditioning, an interval is interposed between the CS and the US. This form of conditioning requires the hippocampus in both rabbits (Solomon et al., 1986) and humans (McGlinchey-Berroth et al., 1997). Studies of elderly normal subjects (mean age = 67 years) given differential eyeblink conditioning (CS+ vs. CS−) suggest that trace conditioning is hippocampus dependent because it requires the acquisition and retention of conscious knowledge during the course of the conditioning session (Clark and Squire, 1998). Only subjects who became aware of the CS-US relationship acquired differential trace conditioning. The correlation between measures of awareness taken after trace conditioning and conditioning performance itself was $r = 0.74$ and $r = 0.69$ for two different trace-conditioning tasks. In contrast, in two tasks of delay conditioning, awareness bore no relationship to conditioning performance ($r = 0.10$ and $r = 0.16$).

Trace conditioning is dependent on the cerebellum as well as the hippocampus (Woodruff-Pak, Lavond, and Thompson, 1985). Thus, a nondeclarative learning circuit in the cerebellum presumably is required for the generation of the conditioned response. Trace conditioning likely requires the hippocampus (and an interaction between hippocampus and neocortex) because the existence of the trace interval makes it difficult for the cerebellum to process the CS and US in an automatic way. With the help of the hippocampus, the neocortex may develop a representation of the temporal relationship between the stimuli, which then can be available to the cerebellum in a format that the cerebellum can use.

Conclusion

It presently is possible to link particular brain regions and systems to particular kinds of memory (figure 53.11). Unlike declarative memory, nondeclarative memory does not depend on a single brain system. These different forms of nondeclarative memory have different properties and different functions. A common thread is their independence from declarative memory and the fact that they are nonconscious. As the functional neuroanatomy of memory is becoming better understood, it should become possible to discover where and how plasticity is occurring in the different circuits that comprise each memory system. This information also would illuminate a number of long-standing systems-level questions about memory: (1) What is a memory system? (2) How independent are the systems from each other? and (3) When memory loss occurs, is the information simply inaccessible or has it been erased?

54 The Anatomical Bases of Memory

HANS J. MARKOWITSCH

ABSTRACT Memory is a basic function for survival of the individual and the species. Its functions are represented in an extensive number of brain structures. Successful storage of information in memory depends on a number of associated functions, among which emotional embedding is of special importance. The combined application of modern neuroradiological, neuropsychological, and neurological methods, which allow the *in vivo* study of the healthy as well as of the damaged brain, has resulted in a degree of functional localization that was unpredictable until recently. Psychological insights into classification of memory along the dimensions of time (short-term memory, long-term memory) and contents (episodic memory, knowledge, procedural memory, priming) and the formulation of neuropsychological mechanisms of information transfer, storage, and retrieval have resulted in the specification of both essential and supportive structural conglomerates or combinations that underlie the acquisition, storage, and retrieval of memory. The division between short-term and long-term memory continues to be useful. Short-term memory depends mainly on cortical association regions, particularly within prefrontal and parietal areas. The transfer of episodes and facts for long-term storage in cortical networks depends on the limbic system. Primed information is processed, and probably stored, in unimodal cortical regions, and procedural information is processed, and probably stored, in subcortical areas—in particular, the basal ganglia and the cerebellar structures. Retrieval of information concerning facts and episodes engages frontotemporopolar regions asymmetrically: The left hemisphere dominates retrieval of facts, and the right hemisphere dominates retrieval of episodes.

Contrary to some traditional views, there is little doubt that memory is represented in many widely distributed areas of the brain. This statement is based not only on the existence of multiple forms of memories and on the likely physiological processes of information transmission by means of cellular processes, but also on the complexity of the mnemonic information itself. Memorizing information usually is an active and complex process that may include attentive and emotional factors and that depends on the constellations and availability of essential and supporting variables. Nevertheless, it is possible to specify, to a certain degree, anatomical bases of the acquisition and retrieval of various kinds of information in the mammalian and human brain.

The selection of topics covered in this chapter is based on two primary considerations: What is basic to mem-

ory, and wherein lie the advances? The basics are given by the organization of memory along the time-related sequence of information processing: acquisition, encoding and consolidation, storage, and retrieval. The advances come primarily from insights obtained by interdisciplinary approaches, including the fields of neurobiology and psychiatry. The more normal findings are the more controversial as well: Are different brain structures involved in information encoding and retrieval? Are there similarities between environmentally induced psychic (psychogenic) forms of amnesia and forms with a clear, measurable anatomical basis? Is memory consolidation time-limited and, if so, what are the limits, and do they depend on the content of the information?

Methods and concepts

As in all fields of science, a discussion of the anatomy of memory also depends on individual points of view of the brain and its evolution and workings. The basic assumptions adopted here include the notions of a common blueprint of neural organization among mammalian species and especially among primates, greater diversity of human memory than that of other species, mnemonic information processing nearly everywhere in the brain, and greater centrality of some brain regions than others for collecting, evaluating, storing, and transmitting the information.

The study of brain/memory relations has grown tremendously in the past few years, owing mainly to the expansion in methods used and increase in the species studied. Basic mechanisms of information transfer are investigated in invertebrates with as simple nervous systems as the mushroom bodies of flies or bees (Connolly et al., 1997), and methods currently employed range from electrophysiological recordings through the study of brain-damaged individuals with neuropsychological tests, to the combination of brain imaging and neuromonitoring methods in normal human individuals (Mangun, 1997). This wide spectrum has resulted in a far more complex but much more integrated view of mnemonic information processing than propagated in previous times (Lashley, 1950).

A considerable impetus for a refined analysis of brain/memory interrelations was provided by various

HANS J. MARKOWITSCH Physiological Psychology, University of Bielefeld, Bielefeld, Germany

FIGURE 54.1 Possible consequences of brain injury on old and new memories.

proposals of the existence of different content-based memory systems (episodic memory, semantic memory) that augmented the time-related organization of memory. These systems, therefore, constitute a pivotal point in the following discussion. The other major classificatory dimension, exemplified in terms such as short-term memory and long-term memory, can create uncertainties because of lack of agreement among different researchers. Thus, for some, short-term memory encompasses hours, for others minutes, and still for others seconds. In this chapter, short-term memory is assumed to cover time periods of seconds to a few minutes at most, and long-term memory is everything beyond. In addition, work with brain-damaged patients has made another distinction necessary, namely that between memories acquired before brain injury (old or retrograde memories) and memories acquired thereafter (new or anterograde memories) (figure 54.1).

Because the contents-specific subdivisions of memory are of more recent origin, they tend to be more controversial. The discussion in this chapter relies on Tulving's terms (see his chapter), because his classification seems to correspond closely to observations of selective memory loss in patients with different forms of brain damage.

Briefly, long-term memory is subdivided into episodic memory, the knowledge system (frequently named "semantic memory"), procedural memory, and priming. Episodic memory is event or autobiographical memory—that is, memory for context-embedded events of one's own past. The knowledge system refers to context-free facts, procedural memory to various (perceptual, motor, cognitive) skills, and priming to enhanced probability of reidentifying of previously perceived stimuli (or, for conceptual priming, stimuli from a previously encountered set or category).

Amnesia and functional localization

Insights into the processing of memory by the brain traditionally were derived from patients (or animals) with brain lesions. Indeed, memory disorders belong to the most common consequences of brain damage. For a long time, and in the neurological literature until quite recently, the failure or lack of memory was simply termed "amnesia." A single gross distinction was made between global amnesiacs and demented patients. Demented patients were amnesic, but they additionally had marked changes in personality (e.g., patients with Alzheimer's disease). Amnesiacs were seen as having preserved intelligence and short-term memory but impaired long-term memory. This simple dichotomy has been replaced with more complex classificatory schemes because clinical research has produced an overwhelming number of case reports on patients with rather special types of memory impairment. Some patients are labeled amnesiacs when their sole mnemonic inability has to do with naming contemporary celebrities (Lucchelli, Muggia, and Spinnler, 1997). Table 54.1 gives some examples of the varieties of amnesia.

The partitioning of amnesia was accompanied by a partitioning of brain loci associated with each form, bringing back the question of functional localization. It is trivial to say that no brain structure acts on its own but rather depends on its inflow and outflow for successful functioning. The popular concept of "disconnection syndrome," which was created some time ago, describes the interruption of a function or ability after focal brain damage without any need to assume that the impaired function or ability was actually "situated" in the damaged area. Nevertheless, one still discerns a strong tendency in the literature to relate specific functions to specific brain regions, a practice that probably is respon-

TABLE 54.1
Examples of amnesic states

Anterograde amnesia	The failure to store new memories long-term
Retrograde amnesia	The failure to retrieve (or ecphorize) old memories
Transient global amnesia	Anterograde (and possibly, although to a lesser degree, retrograde) amnesia for a time period of 1 day or less
Psychogenic amnesia	Retrograde amnesia without (obvious) brain damage, usually as a consequence of strong psychic pressure(s)
Functional amnesia	Retrograde (and in rare instances, also anterograde) amnesia of differing, but at least partly psychic, origin
Topographical amnesia	Inability to remember or retrieve loci in space
Color amnesia	Inability to remember or retrieve the names of colors
Autotopagnosia	An orientation disturbance for the own body or parts of it
Anomia	Inability to remember or retrieve names
Anosognosia	Inability to recognize own illness-dependent functional losses
Reduplicative paramnesia	The phenomenon of being convinced that a person, a place, or an object exists twice
Prosopagnosia	Inability to recognize faces

sible for a good deal of confusion in the field. All serious students of memory pathology would do well to pay careful attention to Chow's (1967) caveats on interpreting interdependencies between the brain and behavior. He proposed that "if a brain lesion fails to affect a learning task, it cannot be stated that this part of the brain is unimportant in normal animals. Second, if the lesion does influence performance of the task, it does not necessarily mean that it is the only neural structure involved. Third, the aim of the ablation methods is in a way never attainable, for it throws away the object (a region of the brain) one wishes to study" (p. 708).

Brain damage and memory

Following are examples of relations between brain damage and aspects of memory. The emphasis is on anatomical networks that are important for different aspects of memory (Mesulam, 1998).

Most of our knowledge on brain/memory interrelations stems from the careful anatomical and neuropsychological study of brain-damaged patients. Modeling of human brain damage by inducing brain lesions in animals has provided additional or confirmatory insights. From the earliest days of scientific brain research, observations of behavioral alterations of brain damaged subjects have constituted nature's teaching book (Markowitsch, 1992). For the field of memory, some kinds of brain damage that occurred regularly as a consequence of a disease process served to establish the basis for functional localization. The Korsakoff syndrome is one of these disease processes that is accompanied regularly by severe memory deterioration, although patients' general intelligence may be largely preserved. The anatomical basis of the syndrome—degeneration of diencephalic nuclei, the mamillary bodies, and the medial thalamic region—already was suspected

around the turn of the 19th century, and this view generally has been confirmed (Mair, Warrington, and Weiskrantz, 1979), leading to the creation of the concept of "medial diencephalic amnesia."

Another impetus for the study of amnesia came from therapeutically induced brain surgery. H.M., the most intensely studied patient, received in 1953 a bilateral resection of major portions of his medial temporal lobes with the consequence of persistent anterograde amnesia (Scoville and Milner, 1957). Again, the historical roots of memory's connection with the hippocampus and the surrounding structures can be traced back to the earliest days of our science (von Bechterew, 1900; Markowitsch, 1992). The study of the hippocampus and memory has continued relentlessly to this day. The most recent observations have pointed to a special role of the hippocampal formation in episodic memory acquisition (Vargha-Khadem et al., 1997). The set of cases with this form of pathology is named "medial temporal lobe amnesia."

More recently, damage to regions in the basal forebrain, usually caused by rupture of the anterior communicating artery, also was found to result in amnesia (Damasio et al., 1985), giving rise to the concept of "basal forebrain amnesia."

What unifies the different forms of amnesia is the fact that all of the damaged regions belong to the limbic system, or at least to its "expanded" form (Nauta, 1979). Consequently, the limbic system can be seen as playing a crucial role in memory processing—a conclusion that also makes good sense from an evolutionary point of view (Markowitsch, 1999). The limbic system, originally called the smell brain or rhinencephalon (Herz and Engen, 1996), was critical for survival of the individual and the species at early stages in evolution. Later, it served in more general ways for the binding and preservation of

emotions and memories (Papez, 1937; Markowitsch, 1994).

Nonlimbic structures have had a less clear-cut role in memory. Damage to neocortical regions was seen as causing either quite restricted forms of amnesia, such as an inability to remember or retrieve names or faces (e.g., Reinkemeier et al., 1997), or—in its more widely spread form, as in Alzheimer's disease—a general intellectual decline, including that in memory. The memory decline in Alzheimer's disease typically is more complete than in amnesia because it also is affected by cortical damage and includes impairment in short-term memory (Belleville, Peretz, and Malenfant, 1996), anterograde and retrograde, episodic and semantic memory (Beatty et al., 1988; Brustrom and Ober, 1996; Daum et al., 1996; Greene, Baddeley, and Hodges, 1996). Depending on the particular combination of damaged cortical surfaces, the patterns of symptoms may shift somewhat, and amnesia is nearly always the core deficit. Pick's disease or frontotemporal dementia represents another example in this category (Knopman et al., 1989; Neary and Snowden, 1996). It must be mentioned, however, that many forms of cortical dementia, and especially Alzheimer's disease, include damage to limbic structures as well, above all of those including and surrounding the hippocampus (Braak and Braak, 1997). Therefore, it seems logical that Hassing and Bäckman (1997) found that cortical dementia diseases particularly affected the ability to transfer information from temporary to permanent storage.

Damage to nonlimbic subcortical structures causes other syndrome pictures in which memory complaints occur less frequently and are less severe. However, again stimulated by the appearance of contents-based memory subdivisions, investigations during the past decade have begun to reveal close relations between severe procedural memory impairments and Parkinson's disease and Huntington's chorea. Conventional neurology had regarded both diseases (and more generally, damage to the basal ganglia) as resulting in major motor impairments, rigidity, tremor, and akinesia for parkinsonism, and choreiform movements for Huntington's chorea—this despite the fact that it was known that (for both forms) progression of the disease process may lead to dementia (“subcortical dementia,” “frontostriatal dementia”; Darvesh and Freedman, 1996; Bäckman et al., 1997). Paralleling the effects of basal ganglia damage, damage to the cerebellum also has been found to result in procedural memory impairments.

To complete this short overview, cortical regions surrounding primary sensory regions, especially the belt zones of unimodal nonprimary cortices, are coming to be seen as controlling priming forms of memory (Nielsen-

Bohlman et al., 1997; Ochsner, Chiu, and Schacter, 1994; Seeck et al., 1997). However, a study by Zhang, Begleiter, and Porjesz (1997), which recorded event-related potentials associated with priming of visual and verbal material, found, for normal subjects, the expected occipitotemporal activation (bilaterally, with some preponderance to the right) for the visual but not the word material. For the word material, a frontal activation (current source analysis), together with some less prominent posterior sources, was observed. Thus, as far as priming is concerned, data that would allow firm inferences and would include all modalities still are lacking (but see chapter 58).

Brain structures implicated in information acquisition, storage, and retrieval

Processing of information usually is induced by environmental stimulation but also may be created internally, that is, from within the brain. For both ways, the principles of divergence and convergence regulate information transmission, distribution, and focusing. Most of the information is transferred from the peripheral sensory (recipient) organs by means of subcortical nuclei to cortical areas. Immediate processing of received information is referred to as working memory (see chapter 50) and is regarded to occur cortically as well, with prefrontal and parietal regions participating. Long-term memory has been more difficult to localize or to correlate with brain regions because both its processing and storage are more diverse. The transfer from short-term to long-term storage probably is the most delicate stage and is related widely to an agglomerate of subcortical and allocortical structures, named the limbic system. Following is an overview of regional networks involved in information encoding, storage, and retrieval. Kornhuber's scheme (figure 54.2) provides an instructive and easy-to-follow model of a possible brain circuitry engaged in information transmission from sensory input to final storage as engram. An added strength of the scheme is that it points to the importance of motivational and emotional factors for memory processing.

AFFECT AND MEMORY Affect is an important dimension for memory-encoding storage and retrieval, and many patients with memory problems have problems in affect as well. Certain structures within the limbic system, especially the septum and the amygdala, stand out against most of the others when it comes to affective information modulation. The amygdala (1) is connected with the hippocampus and (2) represents one of three components of the so-called basolateral limbic circuit (Sarter and Markowitsch, 1985). Damage to the amygdala results in a flattening of emotions (similar to

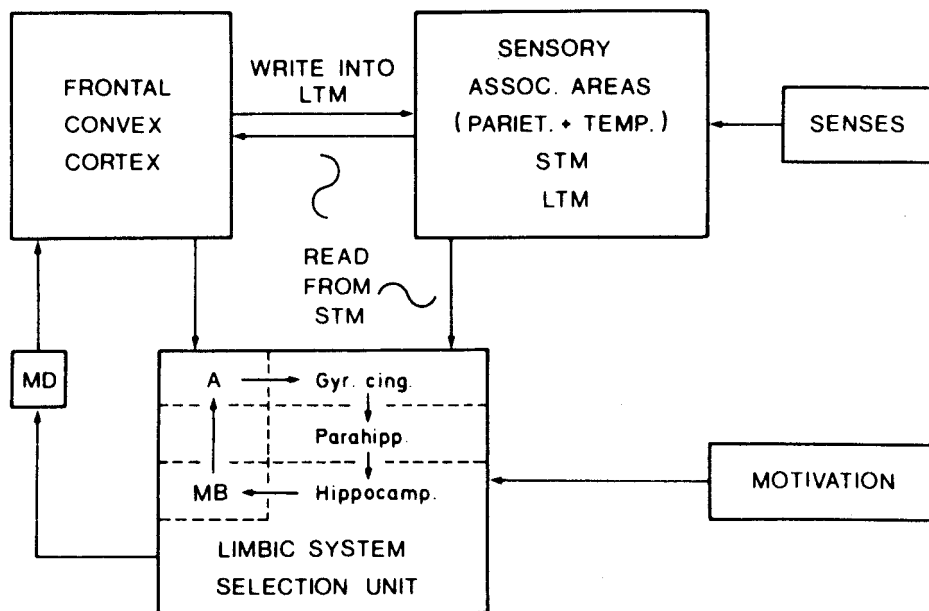

FIGURE 54.2 Kornhuber's (1988) scheme of memory processing emphasizes the posterior association areas of the cerebral cortex as involved in short-term memory (STM) processing, the limbic system (Papez circuit) as involved in the transmission of information from short-term to long-term memory (LTM), and the cortical regions are assumed to basically be the storage places of successfully formed engrams. Interpreting this model liberally, it can be assumed that information enters the brain via the senses, that largely internally created motivational and emotional stimuli interact with the preprocessed sensory information within the "limbic system selection unit," and that information which "harmonizes" or "synchronizes"

with the motivational/emotional state of the organism and which can be further synchronized or associated with already existing (and matching) engrams is transmitted for permanent storage. Note that this scheme (1) holds principally only for episodic memories, (2) says nothing about information retrieval, and (3) gives a very important role to the thalamic mediodorsal nucleus (Markowitsch, 1988). *Abbreviations:* A, anterior thalamic nucleus; Gyr cing, cingulate gyrus; Hippocamp, hippocampus; MB, mammillary body; MD, mediodorsal thalamic nucleus; Parahipp, parahippocampal region. (Reproduced from figure 4 of Kornhuber, 1988, with permission.)

that seen in the Klüver-Bucy syndrome, which occurs after amygdaloid and some additional temporal lobe damage); patients with bilateral amygdala damage may no longer be able to differentiate successfully between relevant and irrelevant information. They consequently fail to successfully encode pertinent new material (Cahill et al, 1995; Markowitsch et al., 1994). Similar deficits may occur after septal damage, which seems to lead to an exaggerated affective engagement that also blurs successful information discrimination and selection (von Cramon and Markowitsch, in press; von Cramon, Markowitsch, and Schuri, 1993).

The basolateral thalamic circuit, composed of the amygdala, the mediodorsal nucleus, and area subcallosa (figure 54.3) most likely supports the action of the Papez circuit by controlling and selecting information of major relevance to the organism. In this sense, it feeds the motivational-emotional content into Kornhuber's Limbic System Selection Unit (figure 54.2). Interruption of this loop may occur after capsular genu infarcts and results in profound memory disturbances (Markowitsch et al., 1990) that have been interpreted as "contextual amne-

sia" (Schnider et al., 1996). A somewhat more extended circuit for mood regulation was proposed by Soares and Mann (1997), who included striatal and ventral pallidar structures and the cerebellum as well.

There also is some evidence that altered affective states that may be caused by prolonged stress or by the appearance of a major stress event reminding a person of a similar one experienced previously (e.g., a life-threatening situation) may change the brain's biochemistry—release and binding of glucocorticoids or of gamma amino butyric acid (GABA) agonists—and may result in an inability to successfully store new information: the mnestic block syndrome (Markowitsch, 1997a; Markowitsch et al., 1998; Sapolsky, 1996). In a few instances, even permanent brain damage in the hippocampus has been found as the likely result of such stressful events (Bremner et al., 1995, 1997).

Of the relevant cases that have been reported, that of a young man who for approximately 8 months lost his ability to form new memories for permanent storage is most interesting (Markowitsch et al., 1998). The patient had seen a fire in his house, and this event seems to have

FIGURE 54.3 The basolateral limbic circuit. Amygdala, mediodorsal thalamic nucleus, and area subcallosa are linked with each other by distinct fiber projections, namely the ventral amygdalofugal pathway, the inferior thalamic peduncle, and

the bandeletta diagonalis. Additionally mentioned is the stria terminalis, which connects the amygdala and the hypothalamus. (Reproduced from figure 5.3 of von Cramon, 1992, with permission.)

induced a shock (mnestic block) condition resulting in anterograde and partial (for the past 6 six years of his life) retrograde memory loss. When he was 4 years old, the patient had seen a man burning to death in his car. Although conventional neuroradiological investigations failed to show any deviations from normal, an FDG-PET (positron emission tomography with 18 fluoro-deoxyglucose) revealed major hypometabolic in zones of the medial and anterolateral temporal cortex and the medial diencephalon (figure 54.4; see color plate 33). The hypometabolic zones can be assumed to correspond to the mnestic deficits.

MEMORY ACQUISITION Memory acquisition usually is divided into the sensory uptake of information, its initial encoding, and further consolidation. Of these time-related subdivisions, sensory uptake is easiest to specify because it refers simply to the engagement of the appropriate sensory receptors, for example, rods and cones in the retina and hair cells in the cochlea, and to the further transmission up to the cortex. There is some controversy as to whether memory encoding and memory consoli-

dation should be viewed as separate processes or whether they in fact constitute a single one (Cermak, 1989, 1997). Usually, however, encoding is viewed as the more initial part of information transmission and consolidation as the more advanced part.

Baddeley (1997) has discussed elaborately the separability of the short-term and long-term memory systems. Although he appeared to be inclined to assume their separation, he did not settle the issue but instead introduced his more complex (multicomponent) working memory model that might be seen as a replacement of the short-term memory system but still adheres to the basic dichotomy. Because this chapter deals with the neuroanatomy of memory and—as also is acknowledged by Baddeley (1997)—especially cases with brain damage, which speak for the existence of a short-term and a long-term store that “could be separately and differentially impaired in different types of patient” (p. 48), the following arguments are based on assuming their existence (see also confirmatory evidence obtained under amytal injection in epileptic patients, Rouleau et al., 1989).

FIGURE 54.4 FDG-PET-based coronal sections from anterior to posterior (left to right) through the brains of a patient with a shock-caused amnesic condition (Markowitsch et al., 1998) (top row) and a control subject (bottom row). Note the reduction in cerebral metabolism in widespread cortical and subcortical areas in the patient, compared with a control sub-

ject's brain at corresponding levels. A regions-of-interest analysis of the patient's regional cerebral glucose metabolism revealed that especially his temporal lobes and his thalami showed a more than 20% reduction compared with those of age-matched men. (Modified after figure 1 of Markowitsch et al., 1998.)

While at first seen as outstandingly exceptional, the number of reported cases with selective short-term memory impairments is increasing (Butterworth, Cipolotti, and Warrington, 1996; Markowitsch et al., in press; Shallice and Warrington, 1970). Usually, the damage is found in the angular gyrus region of the left parietal cortex (figure 54.5; see color plate 34), which indicates that this cortical area is involved centrally in short-term memory processing and therefore in the initial level of information acquisition. Especially revealing are the results from dynamic imaging studies that suggest a role of laterodorsal prefrontal regions in working memory (Casey et al., 1995; Manoach et al., 1997). ("Working memory" can be defined as a system for temporarily holding and manipulating information; Baddeley, 1997.) Consequently, it seems reasonable to assume that both anterior and posterior parts of the association cortex are engaged in the temporary or transient storage of information.

This statement, however, has to be qualified further by reserving it for those forms of information that are ac-

quired explicitly or consciously, that is, as episodic memories. For the other forms of information, a more gradual acquisition process, along the lines of Craik and Lockhart's (1972) depth of processing idea, may be assumed to exist. For these forms, which may include conditioning, cerebellar, amygdaloid, and also various cerebral cortical regions, have been named as relevant (e.g., Knowlton, Mangels, and Squire, 1996; Squire, Knowlton, and Musen, 1993; Thompson and Kim, 1996).

MEMORY TRANSFER The most important part of information processing is its transfer into long-term memory. In Kornhuber's model (figure 54.2), it is assumed that the so-called Limbic System Selection Unit reads the information from the short-term store and selects appropriate portions for transfer into the long-term store. This idea of the limbic system being the central processor for information transfer has a long tradition. Its forefathers may be seen in Papez (1937) and Hebb (1949). Papez

FIGURE 54.5 Three-dimensional reconstruction of the left hemisphere revealing the tumor-caused brain damage (including the penumbra region) of a patient with major short-term

memory impairments. The case has been described by Markowitsch and associates (in press).

had the idea of a circuit within limbic structures, named Papez circuit after him (figures 54.6 and 54.7), and Hebb assumed that information has to circulate within certain brain regions before being transferred for long-term storage.

Although the term *limbic system* is somewhat unclear and is defined differently by differing authors (see Markowitsch, 1999), there is general agreement with respect to its core structures. As aforementioned (see section on brain damage and memory), the region of the medial temporal lobe (which contains the hippocampal formation), the region of the medial diencephalon (including the medial thalamic and the mamillary nuclei), and possibly also the basal forebrain region are included. A number of strong and in part bidirectional fiber bundles interconnect the structures of all three regions (cf. figure 54.6). This arrangement brings up the question of whether the aforementioned three regional systems should be regarded as a unity or as three separable blocks. Squire (1995) suggested that the temporal and the diencephalic blocks probably constitute a single memory system and that evidence for different functional contributions may be difficult to demonstrate.

From an anatomical point of view, it seems justified to embed them and even a number of additional structures in one major memory processing system. Braak and colleagues (1996) have delineated an extensive scheme that represents the components of such an all-inclusive cir-

cuitry (figure 54.8; see color plate 35). It seems likely, however, that even the original regional systems (medial temporal, medial diencephalic, basal forebrain) make different functional contributions. Again, the anatomy can be drawn on to make this suggestion: the mediodorsal nucleus is interconnected most intensely with the prefrontal cortex, the basal forebrain has numerous cholinergic connections with widespread cortical regions, and the hippocampal region is associated widely with the temporal cortex. Insight, the tendency to confabulate, retrograde amnesia, conscious reflection, affective involvement, time perception, and susceptibility to interference are examples of the kinds of features that may differ between the three regional blocks (von Cramon, Markowitsch, and Schuri, 1993; Markowitsch, von Cramon, and Schuri, 1993; Vargha-Khadem et al., 1997).

Nevertheless, bilateral and largely complete damage to the major components (including pathways) of the medial temporal and the medial diencephalic system usually results in persistent amnesia. Each of these structures therefore can be thought of as representing a bottleneck structure through which information has to pass for successful consolidation. Bilateral damage to any of these structures typically results in a disconnection syndrome, which is termed amnesia. There are, however, some exceptions to this inability that question the universal involvement of the limbic system in (episodic) memory transfer. Patient H. M., for example, learned

FIGURE 54.6 The major pathways of the limbic system and the rhinencephalon. 1, cingulum; 2, fornix; 3, stria terminalis; 4, stria medullaris thalami; 5, nucleus anterior thalami; 6, nucleus medialis thalami; 7, nuclei habenulae; 8, tractus mamillothalamicus; 9, fasciculus longitudinalis dorsalis; 10, commissura anterior; 11, tractus mamillofornicalis; 12, tractus habenu-

linterpeduncularis; 13, fasciculus telencephalicus medialis; 14, pedunculus corporis mammillaris; 15, corpus mammillare; 16, ansa peduncularis; 17, bulbus olfactorius; 18, stria olfactoria lateralis; 19, corpus amygdaloideum; 20, hippocampus. (Reproduced from figure 191 of Nieuwenhuys, Voogt, and van Huizen, 1988, with permission.)

the shooting of President Kennedy, the death of his parents, or a melody he loved. These exceptions and some additional arguments have led some researchers to postulate the existence of a nonlimbic, neocortical memory encoding system that is, however, slow and quite limited in its capacity to result in permanent information storage and that also seems to be more prone to encoding of frequently repeated facts than of episodes (Kapur, 1994; McClelland, 1994).

Memory storage

There is little concrete evidence concerning the actual storage of information in the human brain. Animal research indicates that successful information acquisition is correlated with changes in neuronal morphology: synaptic enlargement, dendritic spine growth, expansion of the neuropil, and the like. (Before successful acquisition and morphological alterations, bioelectrical changes such as

long-term potentiation/depression may represent the encoding/consolidation processes.) Furthermore, the evidence of successful retrieval of old information in patients with complete bilateral damage of one of the limbic bottleneck structures assumed to transfer information for long-term storage suggests that none of these (e.g., medial thalamus, hippocampal region) is a long-term memory storage place. Instead, frequently proposed loci for long-term storage of information are the cerebral cortical areas and especially the association or polymodal regions—Kornhuber's scheme (figure 54.2) is an example (Eichenbaum, 1997).

Although it is quite likely that the cerebral cortex is indeed the major storage place for the episodic as well as for the knowledge and the priming systems (neuronal capacity alone favors it [Schaefer, 1960] and also the apparent trace decay in patients with widespread cortical damage [e.g., patients with Alzheimer's disease]), it still is unknown whether singular neuronal modules or

FIGURE 54.7 The Papez circuit interconnecting the hippocampal formation by means of the (postcommissural) fornix to the mammillary bodies, these by means of the mammillothalamic tract (or tractus Vicq d'Azyr) to the anterior thalamus; the anterior thalamus with its cortical projection targets reaches the cingulate gyrus, and the subicular part of the hippocampal formation, and the cingulum fibers in addition project back from the cingulate gyrus into the hippocampal formation. (The pre-commissural fornix in addition provides a bidirectional connection between the hippocampal formation and the basal forebrain.) (Adapted from Irle and Markowitsch, 1982.)

widespread neuronal networks represent particular bits of information. It is not even known in which form and complexity (e.g., singular bits, large-scale agglomerates) an event or item is represented or whether glial cells also might play a role in representation. Furthermore, it is an unsolved question whether cortical regions alone are able to represent an event or whether they might need assistance by emotion-coding regions such as the amygdala or the septum.

Here, it is assumed that information is represented in widespread networks (Abeles, 1992; Bartlett and John, 1973; Fuster, 1997) that nevertheless may have a modular organization (Szentagothai, 1983) as their basis. For the storage of procedural memories, components within the basal ganglia and the cerebellum most likely are relevant. Squire and associates (1993) assumed that storage of skills and habits might occur "at the synapses between cortical neurons and neurons in the neostriatum" (p. 482) (see also Knowlton, Mangels, and Squire, 1996).

MEMORY RETRIEVAL Memory retrieval refers to the use of available stored information. In fact, as pointed out by Tulving (1983) and also evident from the results on "false memories" (Loftus, 1998), environmental conditions determine to a considerable degree the retrieval of information. Tulving (1983) therefore reintroduced the term "ecphory" to describe the process by which retrieval cues interact with stored information so that an image or a representation of the information in question appears. One question is whether in the normal (non-damaged) brain, the retrieval of information occurs in-

dependent of the encoding regions (limbic system) or activates them as well. Because every form of retrieval necessarily leads to simultaneous re-encoding of the just-retrieved information, dynamic imaging studies up to now could not solve this question (e.g., Fink et al., 1996).

A number of findings (e.g., ecphory under hypnosis, ecphory with strong retrieval cues) demonstrates that the nervous system has stored enormous amounts of information of which only minor parts are constantly available without appropriate retrieval cues. The idea that the recall of information may depend on brain regions other than those involved in long-term transfer is a recent one, having arisen only in the last decade. It was prompted by clinical observations of patients with focal brain damage outside of the classical limbic regions who had lost old memories, but who had a preserved ability to successfully form new memories (Kapur et al., 1992; Markowitsch et al., 1993; O'Connor et al., 1992). Shortly thereafter, Tulving and co-workers (1994) formulated their HERA-model (HERA = Hemispheric-Encoding-Retrieval-Asymmetry) on the basis of PET results in normal subjects. They proposed a differentially more prominent left-hemispheric prefrontal activation for memory encoding and a differentially more prominent right-hemispheric one for retrieval. Episodic memories of a more emotional content and of yearlong remoteness have been found to engage temporopolar regions to an even higher extent than prefrontal ones (Fink et al., 1996; Markowitsch, 1997b; Markowitsch, Thiel, et al., 1997) (figure 54.9; see color plate 36).

A combination of inferolateral prefrontal and temporopolar regions consequently was assumed to trigger the retrieval of stored old memories. (Thompson-Schill et al., 1997, made the suggestion that it might not be retrieval per se, but the selection among competing alternatives.) For patients with normal left-hemispheric language representation, it was proposed that mainly right-hemispheric (but also some left-hemispheric) damage of this regional combination results in profound retrograde amnesia for episodic (autobiographical) material (Markowitsch, 1995); the reverse pattern with mainly left-hemispheric damage should result in retrograde amnesia for information of the knowledge system. This hypothesis essentially was confirmed by results from brain-damaged patients (e.g., Calabrese et al., 1996; De Renzi, Liotti, and Nichello, 1987; Kroll et al., 1997).

A special form of the mnestic block syndrome also may occur in memory recall: Patients with psychogenic or functional amnesia (De Renzi et al., 1997) have a block to retrieve stored information of autobiographical character without corresponding brain

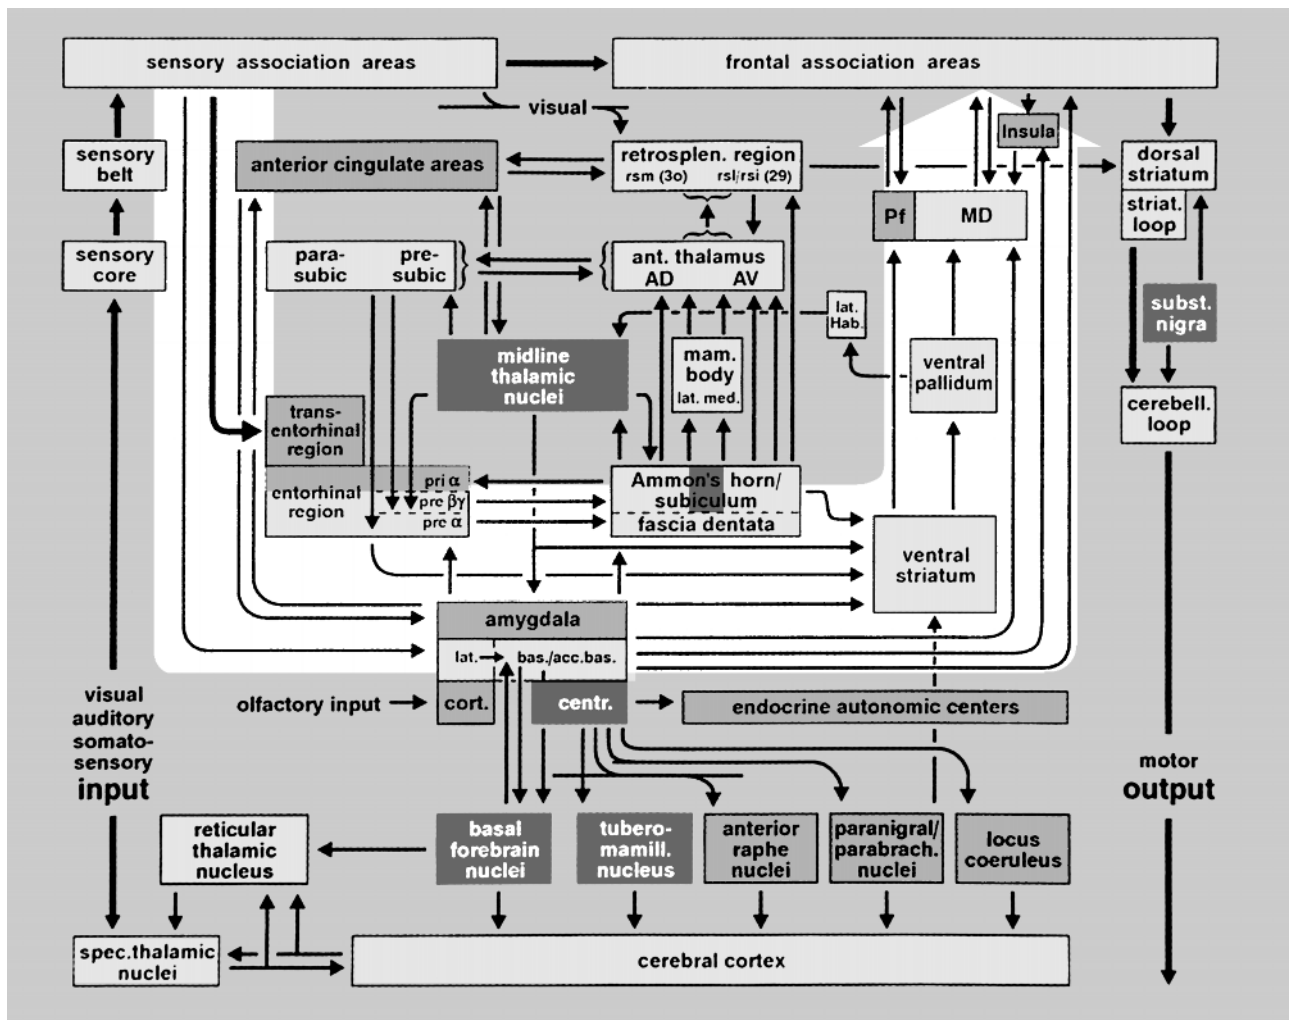

FIGURE 54.8 The limbic loop and additional structures are shown in detail. The amygdala integrates exteroceptive sensory data with interoceptive stimuli from autonomic centers. A large number of amygdalar efferents terminate in nuclei, regulating endocrine and autonomic functions. In addition, the amygdala generates efferent connections to all nonthalamic nuclei that in a nonspecific manner project on the cerebral cortex. *Abbreviations:* ant. thalamus AD and AV = anterodorsal and anteroventral nuclei of the anterior thalamus; cerebell. loop = cerebellar loop; lat. Hab. = lateral habenula; lat., bas., acc. bas., cort., and centr. = lateral, basal, accessory-basal, cortical, and central amygdalar nuclei; mam. body lat. and med. = lateral and medial nuclei of the mamil-

lary body; MD = mediodorsal thalamic nucleus; paranigral/parabrach. = paranigral and pigmented parabrachial nuclei; parasubic and presubic = parasubiculum and presubiculum; Pf = parafascicular nucleus; Pri- α , Pre- β , Pre- γ , Pre- α = layers of the entorhinal region; retrosplen. region rsm (30) and rsl/rsi (29) = medial retrosplenial area (Brodmann's area 30) and lateral and intermediate retrosplenial areas (Brodmann's area 29) of the retrosplenial region; spec. thalamic nuclei = specific projection nuclei of the thalamus; striat. loop = striatal loop; subst. nigra = substantia nigra; tuberomamill. = tuberomammillary nucleus. (After figure 5 of Braak et al., 1996, with permission from Decker Periodicals and Dr. H. Braak.)

damage (Markowitsch, 1996). PET results from a case reported by Markowitsch, Fink, and colleagues (1997) suggest, however, that their brain function may deviate from that of nonamnesic (normal) individuals and may show a brain activation pattern that indicates that such patients indeed fail to ecphorize biographical material because their brain does not engage the proper right-hemispheric frontotemporal trigger structures.

Conclusions

In relation to what was known about the anatomy of memory 5 years ago, it seems reasonable to propose that the basic framework has not been changed. Thus, the differentiation between short- and long-term memory and that between content-based memory subdivisions still motivates questions of functional anatomy, and the study of memory impairment caused by brain damage

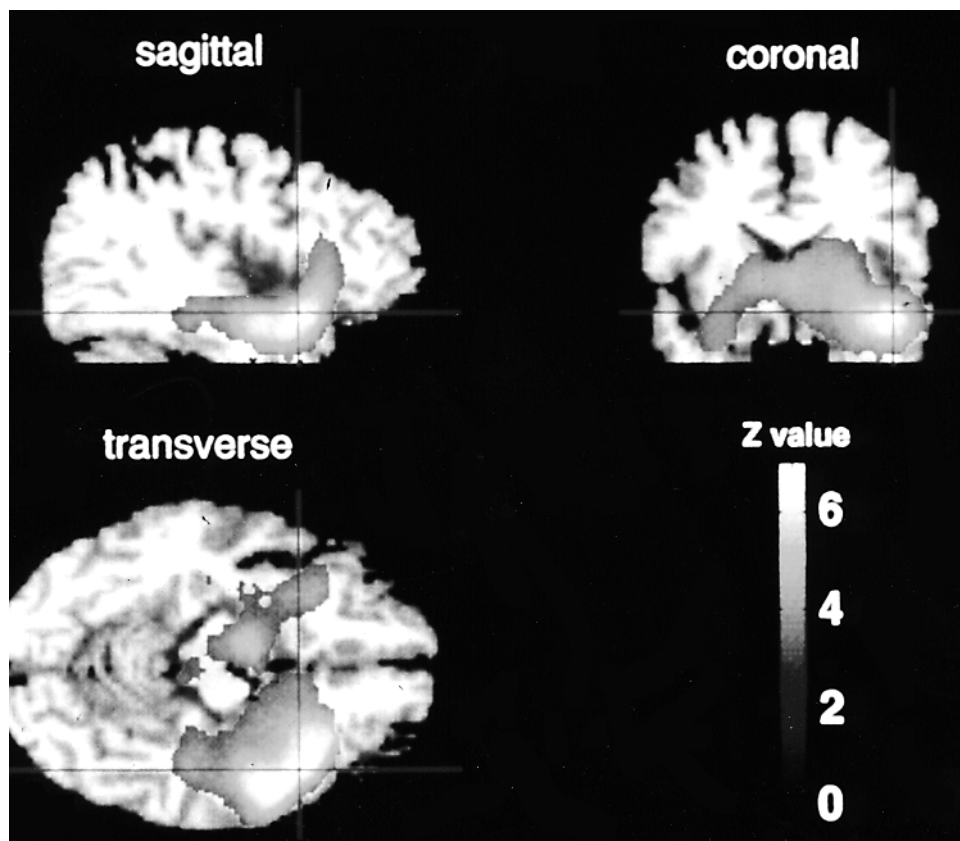

FIGURE 54.9 Positron-emission-tomography (PET) representations of brain activations during euphorizing affect-laden autobiographical memories (displayed on top of arbitrary magnetic resonance images of sagittal, coronal, and transverse brain images). The red cross-hair indicates the local maximum within the area of activation. The color bar indicates the Z statistics achieved. To obtain these activation patterns, PET acti-

vations during euphorizing biographical information from an unknown individual were subtracted from those obtained during euphorizing events from the tested subjects' own biography. Note that the activations are predominantly on the right. (Reproduced with permission from figure 2 of Fink et al., 1996.)

also follows these dimensions. What is new is the enormous expansion of converging data obtained with functional imaging studies and by descriptions of single cases (see, e.g., the newly established journal *Neurocase*, which specializes on single cases). Furthermore, there currently is a much higher degree of convergence from a wider range of disciplines than a few years ago. For example, the biologically oriented psychiatry recently has provided a lot of evidence for brain changes that are related to observed memory impairments. Similarities between environmentally related (“psychic”) and organically caused brain changes and amnesia are documented increasingly. Animal research is supportive in this endeavor from various perspectives.

The medial temporal lobe still is in the center of memory research. Questions concern the contributions of individual regions—for example, the hippocampus proper or the entorhinal cortex—in information processing; here research with nonhuman animals is used to unravel the microcircuitry of the kind that patient studies

usually cannot provide (Murray, 1996). Also, direct injections of neuroactive drugs are used to attack questions such as that on the independence of time-related memory subsystems (Izquierdo et al., 1998). Time and the hippocampus is another issue that is hotly debated: What is the duration of consolidation and how necessary is the hippocampus for long-term retrieval of information? Although much evidence speaks for a time-limited role of the hippocampal region (Knowlton and Fanselow, 1998), exceptionally more extreme positions have recently been proposed (Moscovitch and Nadel, 1998). Finally, the role of the hippocampal formation for different subsystems of content-related memory (episodic vs. semantic memory) is in dispute (Vargha-Khadem et al., 1997; Tulving and Markowitsch, 1998).

The representation of memory in the human brain (as well as its loss—forgetting) remains one of the major riddles of neuroscience. Unraveling the circuits, networks and neurophysiological actions involved in the processes of information input and output helps to identify

the brain's mechanisms for information storage. A dis-closure of the relevant structures and fiber tracts engaged in information transfer also helps to select methods for treatment of memory disorders after brain damage. The detection of commonalities and differences in memory disturbances after various forms of focal brain damage elucidates the degree to which brain regions work in a modular and complementing form and to what degree they are part of a common network whose damage at one point leads to disconnection and major memory failure. The combined application of modern neuropsychological, neurological, and neuroradiological methods provides opportunities in this endeavor that would have been classified science fiction even a few years ago.

55 Psychopharmacological Approaches to Human Memory

H. VALERIE CURRAN

ABSTRACT A range of psychoactive drugs affect memory, often impairing some aspects of memory while sparing others. Such drugs therefore can provide useful tools for exploring the neurochemical bases of memory and memory disorders. This chapter provides an overview of research on the psychopharmacology of human memory. It looks at why studies of the effects of drugs on memory are theoretically relevant before presenting a summary of the mnemonic effects of the two most widely studied classes of drugs—cholinergic compounds and benzodiazepine receptor ligands. Areas of controversy are discussed, focussing on the degree to which the specific memory effects of psychoactive drugs can be distinguished from their nonmemory effects. These issues also are considered in discussing drug treatments aimed at ameliorating cognitive dysfunction in Alzheimer's disease.

Psychopharmacology is the study of the psychological effects of “psychoactive drugs”—drugs that act on the central nervous system. By using pharmacological knowledge of how a particular drug affects neurotransmitters, psychopharmacologists aim to relate brain chemistry to psychological changes induced by a drug.

The second half of the 20th century has seen a rapid development of new psychoactive drugs. These include many new therapeutic agents used to treat psychological disorders such as depression (e.g., fluoxetine [Prozac]), anxiety (e.g., alprazolam [Xanax]), or schizophrenia (e.g., clozapine [Clozaril]). They also include drugs that can help to slow down cognitive decline in progressive dementia like Alzheimer's disease (AD). Many other psychoactive drugs are used recreationally rather than therapeutically, and these include legal drugs, such as alcohol and nicotine, as well as various illegal substances.

There is a reciprocal interaction between the development and use of drugs for therapeutic purposes and the use of drugs as tools to understand the basis of the mind and mental disorders. This interaction is central to research on the psychopharmacology of memory. A range of psychoactive drugs affects memory, often impairing some aspects of memory while sparing other aspects. Because new drugs are developed with ever-increasing

specificity in terms of their neurochemical actions, researchers have a wider pharmacological tool kit with which to explore memory.

Studies of drug-induced amnesia have certain methodological advantages over studies of amnesia in brain-damaged patients. Drugs can be used to induce an amnesia that is temporary and reversible; the degree of amnesia can be manipulated by using different dose levels. By using a placebo condition (i.e., giving a chemically inert substance), each participant can act as their own control. In studies of brain damage, the effects of lesions in different brain areas necessarily involve comparisons between different patients; in psychopharmacological studies, the effects of several different treatments can be examined in the same person. Because healthy people often are the participants in such research, sample sizes can be large enough to create a powerful study. Characteristics of volunteers, such as age, psychopathology, or organic state, also can be varied.

Although these methodological advantages are present, psychopharmacological studies of memory also have certain disadvantages, many of which relate to the lack of specificity of the pharmacological compounds that currently are available. Most drugs have a diffuse effect on the brain, and there is no drug that *only* affects memory. Some drugs produce sedation, and this can have knock-on effects on performance of a wide range of tasks. Therefore, one issue addressed later in this chapter is that of *specificity* of amnestic effects of drugs.

There are some clinical circumstances in which drug-induced amnesia is viewed positively. Anesthesiologists value drugs that induce amnesia because they want to ensure that patients have no recollection of events during their operation. More recently, there has been renewed interest in studies of drugs and memory during anesthesia as a way of studying the role of consciousness in memory (Andrade, 1996). When patients are anesthetized fully and therefore thought to be unconscious, researchers have sought to determine whether they can remember anything from their operation despite global anesthesia. In general, there is more evidence of a degree of preserved memory when implicit rather than

explicit memory tests are used, although findings overall have been conflicting (Ghoneim and Block, 1997).

Drug studies clearly are critical in the development of new pharmacological treatments aimed at ameliorating organic cognitive dysfunctions. To date, researchers have been more successful in creating amnesia with drugs than they have in finding compounds that enhance memory in organic disorders. However, we can learn from memory-impairing drugs: If by inhibiting a neurotransmitter a drug impairs memory, it may be that a drug designed to stimulate that neurotransmitter will enhance memory. A few "antidementia" drugs have been shown to slow the rate of cognitive deterioration in some patients with AD, and this has fired hope that new, more effective treatments soon may be discovered.

Memory and pharmacology: The theoretical context

Many drugs have differential effects on performance on different memory tasks, and thus, drugs can allow us to draw dissociations between different aspects of memory. In this way, they can be complimentary to research with brain-damaged people or research showing functional or developmental dissociations (Nyberg and Tulving, 1996). Drugs known to have particular effects on a neurotransmitter can be used as chemical probes to study the functional role of that neurotransmitter in memory. For example, we know that in AD, postmortem brains show a marked depletion in one neurotransmitter—acetylcholine (ACh)—as well as less marked depletions in several other of the estimated 50+ neurotransmitters in the brain. To examine what role ACh plays in memory, many researchers have given a drug that blocks the action of ACh in normal, healthy subjects (Kopelman and Corn, 1988). The pattern of memory impairments induced by the drug is then compared with that seen in AD.

Another example stems from the robust amnesic effects of a group of drugs called benzodiazepines, which have well-known commercial names like Valium (diazepam), Xanax (alprazolam), and Halcion (triazolam). Thirty years after the discovery of these drugs, specific benzodiazepine receptors were identified in the brain. These receptors are found in greatest concentrations in the cerebral cortex and limbic system (including the hippocampus and the amygdala), areas that neuropsychology has long implicated in memory. Why we all should have benzodiazepine receptors regardless of whether we have ever taken a benzodiazepine is an intriguing question. It suggests that there must be a natural substance (an endogenous ligand) that binds to those receptors, and that such natural ligands play a role in the normal regulation of memory processes. Thus, benzodiazepines have been useful not only as tools to study pharmaco-

logical amnesia, but also in providing a potential keyhole on the brain's natural chemistry.

The mood-altering properties of psychoactive drugs also can offer tools in looking at the relation between mood and memory. For example, an elegant series of studies by Cahill and associates (1995) has shown that one drug, propranolol (which blocks beta-adrenergic receptors) impaired normal subjects' recall of emotionally arousing (but not neutral) elements of a story. Using the same task with two patients who had bilateral damage to the amygdala, they found a similar pattern of memory for the emotional and neutral story elements. Together with evidence that the neurotransmitter, noradrenaline, is released in the rat amygdala in response to learning to avoid an aversive stimulus, Cahill and colleagues suggest that their findings imply that adrenergic function in the amygdala mediates memory for emotional material. It also might be suggested that noradrenergic function mediates arousal or attentional function rather than memory. Nevertheless, these studies illustrate how neuropsychological and psychopharmacological studies can be used in parallel in research on memory.

CHOLINERGICS AND BENZODIAZEPINES Psychopharmacological studies have researched two classes of drugs far more than any others: cholinergics and benzodiazepines (BDZs). Interest in cholinergic drugs was stimulated by the cholinergic hypothesis of AD after observations of marked cholinergic depletion in the brains of patients with this devastating disease. Thus, cholinergic drugs have been the most frequently explored pharmacological strategy in terms of enhancing memory in AD. Further, drugs such as scopolamine (hyoscine), which act as cholinergic blockers, are used to study the functional role of ACh in memory.

Since the original work of Drachman and Leavitt (1974), the amnesic effects of this drug have been studied extensively, and scopolamine was put forward as a "pharmacological model" of AD (Weingartner, 1985). Scopolamine is a selective antagonist at muscarinic ACh receptors, which at high doses also acts an antagonist at nicotinic receptors. Its effects can be attenuated if not fully reversed also by giving an agonist like physostigmine or arecoline. Scopolamine's effects only partially parallel the memory deficits observed in AD. The drug does not mimic the extensive retrograde memory loss or the range of working memory impairments seen in AD. Despite this, the "scopolamine model" remains widely used currently in early tests of potential cognitive enhancing drugs on the basis that if a drug can reverse or ameliorate the temporary amnesia induced in healthy volunteers by scopolamine, it may be effective in the cholinergic depletion of AD.

The amnesic effects of benzodiazepines, initially recognized by anesthetists, were less welcome for the millions who took these drugs on a daily basis for anxiety disorders or insomnia. It was suggested that the administration of benzodiazepines to normal, healthy subjects may provide a useful model of Korsakoff's disease (Weingartner, 1985), although these drugs do not produce the retrograde impairments seen in this disease.

Benzodiazepines act by means of specific benzodiazepine receptors and facilitate the transmission of gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the brain. Like diazepam, lorazepam, and 30 or more similar compounds, BZDs act as agonists at the GABA_A-BDZ receptor (the single term benzodiazepine used here refers to these full agonists). A benzodiazepine antagonist such as flumazenil can block the same benzodiazepine receptor. Compounds also exist that have opposite effects to benzodiazepines at the same receptor—beta-carbolines act as inverse agonists to inhibit the transmission of GABA. Several other compounds act as partial agonists, binding to the receptor but producing less effect than full agonists.

Anterograde “amnesia” is a consistent finding from volunteer studies of single doses of a benzodiazepine or scopolamine: Information presented after the drug is administered is poorly remembered. In contrast, no study has found objective evidence of retrograde impairments of memory: Information acquired before drug administration is retained intact. These drugs therefore impede the acquisition of new information. The degree and duration of anterograde amnesia depends on several factors (dosage and route of administration; the memory assessments used; the times postdrug at which information is presented and retrieval is required; characteristics of the subject population tested; for the benzodiazepines, the particular benzodiazepine taken). Although there is considerable variation between studies in these factors, the relatively large number of studies carried out to date allows some generalizations to be drawn out.

In general, tasks requiring remembering a few items for a period of seconds (e.g., digit span, block span) are unaffected by benzodiazepines or scopolamine. In more complex tasks in which information is manipulated while it is retained, benzodiazepine- and scopolamine-induced deficits are found (Kopelman and Corn, 1988; Broks et al., 1988). On the whole, the evidence points to a reduction in the speed with which information is processed rather than qualitative effects on components of working memory. For example, error rates generally are affected much less than response times (Rusted, 1994).

There is considerable debate among cognitive psychologists about how to characterize long-term remem-

bering in terms of systems, processes and functions, and a parallel debate about what common terminology we might use to describe memory or the dissociations found in performance on memory tasks. Although psychopharmacological dissociations are relevant to this debate, the debate itself is not within the remit of the present chapter. For discussing drug effects on memory, Tulving's memory systems account (Tulving, 1985; Tulving and Schacter, 1990) is used because it most neatly embraces current findings.

A consistent and robust finding is that benzodiazepines and scopolamine impair performance on tasks that place demands on episodic memory. This impairment clearly is dose dependent. Overall, when direct or explicit assessments of memory are used, the experimental manipulations that affect the performance of normal (nondrugged) participants produce a broadly parallel pattern of influences on the performance of participants administered single doses of benzodiazepines. Thus, if subjects are required to process information at different depths, from the relatively superficial (e.g., deciding whether a word is in capital letters or in small case) to the relatively deep (e.g., deciding whether a word belongs to a particular semantic category), benzodiazepines result in fewer words being subsequently recalled but the pattern of recall is the same as normal (i.e., deeper levels of encoding lead to better recall) (Curran et al., 1988; Bishop and Curran, 1995). Rehearsal effects are normal with benzodiazepines, and after acquisition, forgetting rate is not affected by benzodiazepines or scopolamine (Kopelman and Corn, 1988). Further, benzodiazepines do not increase susceptibility to interference when initial acquisition levels on drug and placebo are matched (Gorissen, Curran, and Ehling, 1998).

Many pharmacological studies have used verbal learning tasks to “assess” episodic memory, often implicitly assuming a one-to-one relationship between a task and the episodic memory system. However, many verbal learning tasks are only minimally episodic in nature and performance depends on other memory systems, such as working memory and semantic memory. As Wheeler and colleagues (1997) discuss in their comprehensive review, the essence of episodic memory is enabling “mental time travel”—the capacity to remember in the sense of re-experiencing events in subjective time. Thus “episodic recollection is infused with autonoetic awareness of one's existence in subjective time” (Wheeler, Stuss, and Tulving, 1997, p. 349). Experiential approaches using the remember-know paradigm (Tulving, 1985; Gardiner and Java, 1993) are increasingly giving support to a distinction between “remembering” in the sense of re-experiencing as a participant in an event and “knowing” in the sense of a personally detached observer of an event.

Using the “remember-know” recognition paradigm, two studies have shown that “remember” responses are reduced by benzodiazepines (Curran et al., 1993; Bishop and Curran, 1995). However, “know” responses are not reduced (and can be somewhat increased) by these drugs. This pattern of drug effects parallels that on other tasks tapping episodic and semantic memory, supporting the notion that “know” responses tap semantic memory. Retrieval of well-established (semantic) knowledge generally is intact after drug administration (Ghoneim and Mewaldt, 1990; Polster, 1993). For example, verbal fluency is unaffected by drugs, and in sentence verification tasks, error rates are not increased although drugs often increase the time to complete the task. Further, conceptual priming in category generation tasks is intact following administration of benzodiazepines and scopolamine even though subjects’ explicit recall of studied category exemplars showed marked impairment (Bishop and Curran, 1998). Taken as a whole, these findings therefore provide evidence that episodic and semantic memory can be dissociated pharmacologically.

The contents of episodic and semantic memory are directly accessible to consciousness—we can bring to mind both personal episodes and impersonal facts. In contrast, procedural memory is expressed indirectly through skilled performance. Benzodiazepines do not affect procedural learning in perceptual-learning tasks (e.g., mirror reading) or in anagram-solving tasks (Ghoneim and Mewaldt, 1990). In tasks that have a significant motor response component or where speed of reaction time is critical (e.g., pursuit rotor, serial reaction time), a drug effect may be found, but this usually is a general slowing of performance that relates to the drug’s sedative effect (Nissen et al., 1987; Curran, 1991). Critically, learning *curves* on drugs tend to parallel those on placebo.

Tasks assessing procedural memory in these ways are indirect tests of memory—remembering is inferred from changes in the performance of a skill. Another kind of indirect test of memory includes what is usually termed “priming”: the influence of prior exposure on subsequent performance. As already noted, there is some evidence that conceptual priming is intact after administration of benzodiazepines and scopolamine. Perceptual priming studies with drugs have produced an intriguing finding that one benzodiazepine, lorazepam, produces impairments on standard tasks tapping perceptual priming (e.g., word-stem, word-fragment, and degraded picture identification). Even though benzodiazepines as a class are chemically very similar and all produce impairments on explicit memory tasks, a range of other benzodiazepines (alprazolam, triazolam, diazepam, oxazepam, midazolam), as well as scopolamine, leave perceptual priming intact.

Originally noted by Brown and associates (1989), the effect of lorazepam on perceptual priming has been replicated and extended by several groups of researchers (Knopman, 1991; Curran and Gorenstein, 1993; Vidailhet et al., 1994; Stewart et al., 1996). Task purity criticisms can be applied to some earlier studies on the grounds that explicit impairments contaminated performance on the “implicit” task. However, these could not explain findings of several studies that compared lorazepam with another drug (a different benzodiazepine or scopolamine) that produced the same degree of impairment on an explicit task but showed only that lorazepam impaired perceptual priming (e.g., Sellal et al., 1992; Bishop, Curran, and Lader, 1996). Vidailhet and colleagues (1996) used Jacoby’s “process dissociation procedure” (Jacoby, 1991) to examine perceptual priming effects of diazepam and lorazepam. Although findings overall were not clear-cut, when the deleterious effect of the two benzodiazepines on conscious uses of memory were matched carefully, only lorazepam impaired the automatic use of memory. Using experimental manipulations in accordance with Schacter’s retrieval intentionality criterion, we found that lorazepam impaired word-stem completion and this effect was attenuated by coadministration of the benzodiazepine antagonist, flumazenil (Bishop and Curran, 1995). One could speculate that there is a second population of benzodiazepine receptors, perhaps concentrated in occipital areas, to which lorazepam and flumazenil bind but not other benzodiazepine receptor ligands. Benzodiazepine receptor subtypes have been identified but their functional significance is not known.

Thus, although all benzodiazepines produce impairments of episodic memory, one benzodiazepine, lorazepam, impairs perceptual priming. Because this one benzodiazepine is qualitatively different from others in its effects, this lends support to the notion of perceptual representation systems that are distinct from other memory systems (Tulving and Schacter, 1990).

SPECIFICITY OF DRUG EFFECTS ON MEMORY An ongoing debate in research on the psychopharmacology of memory centers on the specificity of drug effects on memory. At a psychological level, there is the question of how much a drug’s apparent effects on memory can be seen as by-products of its effects on arousal or attentional functions. At a pharmacological level, there is the question of the overlap in patterns of memory effects of drugs with differing pharmacological actions.

Memory and arousal

Benzodiazepines and scopolamine produce dose-related reductions in arousal, and this may contribute to decre-

ments in performance on tasks tapping episodic memory. How can specific mnemonic effects of drugs be differentiated from their effects on arousal? Five main approaches are summarized in table 55.1. For example, one way of dissociating sedation and amnesia would be to show that tolerance over repeated doses of BZDs builds up differentially to the two effects. Tolerance reflects neuronal adaptation to a drug whereby the same dose has less of an effect over repeated use. A general finding is that tolerance develops to drugs' sedative effects fairly quickly, but tolerance to amnestic effects develops over much longer time periods and may not develop fully after several years. Another way of dissociating memory and arousal is to demonstrate differential dose-response curves on the two measures (Weingartner et al., 1995; Smirne et al., 1989).

In a number of studies, benzodiazepine antagonists and agonists were given to see whether there is differential reversal of amnestic and sedative effects by an antagonist. On the whole, studies with flumazenil have produced an inconsistent pattern of results as different agonist/antagonist dosages as well as different procedures have been used. A fair conclusion probably is that sedative and attentional effects are reversed more easily, and at lower antagonist doses, than amnestic effects. However, another method of dissociation has been to show that different drugs may produce the same effect on sedation but different effects on memory, or vice versa. For example, in a comparison of the effects of a sedative antihistamine (diphenhydramine) with scopolamine and the benzodiazepine lorazepam, 50 mg of the antihistamine produced similar sedation levels to scopolamine and lorazepam (Curran et al., 1998). However, unlike scopolamine and the benzodiazepine, it did not produce any impairment on a task tapping episodic memory (continuous word recognition). Event-related potentials (ERPs) also were recorded and showed that all three drugs affected earlier components of ERPs sim-

ilarly, whereas later components such as P₃₀₀ were affected more by scopolamine and lorazepam than the antihistamine.

Psychopharmacologists would welcome drugs that had a range of memory and arousal effects (improving as well as impairing) that would enable double-dissociations to be drawn. However, taken together, results from studies assessing co-occurrence of sedative and memory effects in these different ways provide strong evidence that benzodiazepines and scopolamine have specific effects on memory over and above their sedative effects.

Memory and attention

It could be argued that drugs might reduce attentional resources and thereby impede encoding of information. Gorissen and Ehling (1998) carried out two experiments in which participants were given dual tasks. They performed a visual discrimination task of varying levels of complexity concurrently with a paired-associate learning task. The benzodiazepine diazepam (15 mg) impaired subsequent recall of paired associates, but the level of impairment did not interact with the level of complexity of the visual discrimination task. Although dividing attention did reduce people's memory performance, it was no more disruptive to those given diazepam than to those given placebo. This suggests that reduced attentional resources cannot account for the amnestic effects of benzodiazepines.

The issue of whether amnestic effects are related to impaired attentional functions is a particularly heated debate in the scopolamine literature (Broks et al., 1988; Kopelman and Corn, 1988; Lawrence and Sahakian, 1995). Having concluded from her earlier elegant studies using dual-task paradigms that scopolamine produced impairments of the central executive component of working memory, Rusted (1994) argues that this is not sufficient to explain the drug's effects on attention and

TABLE 55.1
Methods for dissociating drugs' specific effects on memory (M) from their effects on arousal (A)

Method	Typical Findings	Examples
Differential tolerance to drug's arousal and memory effects over repeated dosing	Tolerance to sedation develops before tolerance to memory effects	Ghoneim et al., 1981; Curran et al., 1994; Tata et al., 1994
Differential dose response curves for arousal and amnestic effects	M and A effects show different dose-response curves	Weingartner et al., 1995; Smirne et al., 1989
Differential reversal of agonist effects on A and by antagonist	Variable—depends on ratio of doses of agonist and antagonist	Hommer, Weingartner, and Breier, 1993; Curran and Birch, 1991
Equate effects on A and show differential effects on M	Different drugs produce same A effects but different M effects	Curran, Schiffano, and Lader, 1991; Curran et al., 1998
Statistical (e.g., covariance)	Covariance of arousal measures leaves significant memory impairment	See reviews: Ghoneim and Mewaldt, 1990; Curran, 1991

memory. Impairment of a unitary resource allocator like the central executive would mean that attentional and memory impairments should occur together, and as Rusted shows, this clear correspondence is not often found in studies of scopolamine. Attention is an umbrella term and it may be that different neurobiological systems mediate different aspects of attention. Studies in which a range of attentional tasks have been used show that scopolamine has effects on some but not other aspects of attentional functions (Brooks et al., 1988). Indeed, there is increasing evidence for the role of the catecholamines, especially noradrenaline, in attentional processing (Robbins and Everitt, 1995; Coull et al., 1995). A similar issue of “umbrella terms” also arises with the conceptually ill-defined but psychopharmacologically necessary concept of arousal. Different measures of arousal often bear little relationship to each other, and Robbins and Everitt (1995) argue that different aspects of arousal are mediated by different neurotransmitter systems.

Memory: Pharmacological specificity

As we have seen, the cholinergic blocker scopolamine produces a profile of memory effects that are broadly similar to benzodiazepines. Despite the different pharmacological actions of these compounds, their amnesic effects have proved difficult to differentiate. Two main differences have been noted. First, scopolamine differs from one benzodiazepine (lorazepam) because it does not impair perceptual priming. Second, patients with AD show an increased sensitivity to the detrimental effects of anticholinergics such as scopolamine but no increased sensitivity to benzodiazepines like lorazepam (Sunderland et al., 1986). However, similarities are more pervasive, with both scopolamine and benzodiazepines producing marked anterograde impairments of episodic memory while leaving semantic, procedural, and working memory relatively intact. This similarity in effects may reflect a common neuropharmacological action because GABA inhibition influences cholinergic projection pathways (GABA-ergic mechanisms may inhibit cholinergic activity in the cortex by means of interaction at the level of the basal forebrain). In research with rats, one study showed that injection of a benzodiazepine into the medial septum reduced ACh release in the hippocampus by 50%, whereas injecting the benzodiazepine antagonist flumazenil increased hippocampal ACh release by 95% (Imperato et al., 1994). These kinds of studies are beginning to reveal the interaction between different neurotransmitters and neuromodulators in memory (see McGaugh and Cahill, 1997). Inhibition of long-term potentiation (LTP) in the hippocampus may be a common neuropharmacological effect of benzodiazepines and scopolamine.

PHARMACOLOGICAL STRATEGIES FOR ENHANCING MEMORY FUNCTION In terms of strategies for enhancement of memory, the largest effort is directed toward the development of treatments for AD. Although several neurotransmitters have been implicated in AD (for review, see Curran and Kopelman, 1996), cholinergic depletion still is the most well-documented neurochemical loss, and much effort has focused on compounds designed to correct or moderate this cholinergic deficit. The most widely discussed strategy has been to inhibit the enzyme acetylcholinesterase (AChE). Acetylcholinesterase inhibitors prevent the hydrolysis of synaptically released ACh and therefore increase the efficiency of cholinergic transmission. Tacrine (tetrahydroaminoacridine) was the first antidementia drug to be given approval by the U. S. Food and Drug Administration (FDA), followed by two other AChE inhibitors, donepezil hydrochloride (“Aricept”) and rivastigmine.

Both tacrine and donepezil have modest effects of slowing down the rate of cognitive deterioration over time in patients with mild to moderate AD. Side effects can be problematic, and only a proportion of patients show cognitive improvement with treatment (Knopman, 1995). There is substantial clinical heterogeneity in patients meeting diagnostic criteria for AD and various “subtypes” of AD have been suggested on the bases of neuropathological or cognitive variations (Richards, 1997). It is possible that different clinical subgroups show a different response to different pharmacological treatments.

It is not clear to what extent these drugs produce any specific improvement in memory functions. Sahakian and associates (1993) showed that tacrine improved choice reaction time and improved performance on a task in which patients learned to follow a simple rule and then reverse this rule. However, it had no effect compared with placebo on any memory task, leading Sahakian and colleagues to argue that tacrine improved attentional functions and to suggest that the cholinergic system is implicated in the control of attentional rather than memory processes.

Cholinergic agonists like nicotine increase the effect of ACh either directly or by sensitizing the receptor site. There is evidence that AD is associated with a reduced number of nicotinic cholinergic receptors and that tacrine increases the number of nicotinic cholinergic receptors in patients with AD (Nordberg et al., 1992). Subcutaneous nicotine improves AD patients’ speed of information processing but does not affect performance on memory tasks (Lawrence and Sahakian, 1995), again suggesting that the cholinergic system is involved in attentional rather than memory function.

Evidence from animal studies has implicated nerve growth factor (NGF) as a possible mediator of cholinergic

depletion in AD (when NGF is given to animals, cholinergic function is increased). Other approaches have shown some promise in AD, such as estrogen therapy in postmenopausal women and Vitamin E. A range of non-cholinergic techniques currently are being explored, including vasodilators, so-called "nootropics"—putative cognitive enhancers like piracetam, and a range of other compounds (e.g., neuropeptides, opiate antagonists, benzodiazepine inverse agonists). There also are neurotropic agents such as oligonucleotides that are intended to modify biosynthetic pathways involved in generation of AD pathology. Whether any of these agents have potential to improve cognitive function in AD is not yet known.

Conclusions

This chapter has focused mainly on drugs that impair memory and mainly on the most widely studied drugs, benzodiazepines and scopolamine. Studies of noradrenergic drugs have shown effects on arousal and attention rather than memory. At least 50 neurotransmitters probably exist, although most drugs act on just a few of these, and we are only beginning to explore the complexities of memory's neurochemistry. A large body of animal research has implicated the glutamatergic N-methyl-D-aspartate (NMDA) receptor in memory. In humans, the NMDA receptor antagonist, ketamine, produces memory and attentional impairments (as well as unpleasant psychotic-like symptoms) (Malhotra et al., 1996).

Psychopharmacologists studying memory are reliant on their tools—the chemical probes that are available, and at present, many of these have diffuse effects. Ever more specific pharmacological agents are being produced that will greatly aid researchers to tease apart the neurochemical substrates of memory. The use of radiolabeled drugs in imaging studies are already allowing delineation of receptors in the living brain, and this may provide a means of assessing abnormalities in receptor populations in neurological and psychiatric disorders. A drug and placebo also can be administered during functional imaging and this allows drug-induced changes in activation to be monitored during performance of a memory task (Fletcher et al., 1996). Psychopharmacology will progress enormously given refinements in both the drugs available and the techniques for studying their effects.

56 Memory Retrieval: An Electrophysiological Perspective

MICHAEL D. RUGG AND KEVIN ALLAN

ABSTRACT Event-related potential (ERP) studies of indirect and direct memory tasks have identified retrieval-related neural activity that onsets at approximately 200 to 250 ms post-stimulus. This activity is sensitive to variables that selectively influence item-specific implicit (unaware) memory and differs in its scalp distribution from neural activity engaged during the retrieval of explicit (aware) memories. These findings support the view that implicit memory and explicit memory engage distinct retrieval processes and give insights into their relative timing. Other studies, contrasting ERPs elicited by items that were explicitly recognized on the basis of “recollection” or “familiarity,” have failed to find evidence in favor of the idea that these two kinds of memory are supported by qualitatively different processes. The findings from these studies indicate, however, that multiple processes support recollection. Whereas some of these processes support the retrieval of information from episodic memory, other, “postretrieval” processes are required to make the products of retrieval available to current behavioral goals.

In this chapter, studies employing event-related brain potentials to investigate the neural correlates of human memory are reviewed. Because event-related potential (ERP) studies of memory published before 1995 are already the subject of comprehensive reviews (Johnson, 1995; Rugg, 1995a, b), these studies are not discussed in any detail in this chapter. We focus on the area—item-specific long-term memory retrieval—in which progress since 1994 has been both substantial and cumulative, leaving aside topics such as encoding, working memory, and semantic memory, where, at the time of writing, there is little to be added to the content of the reviews just cited.

Event-related potentials and memory

Event-related potentials represent scalp-recorded changes in brain electrical activity (electroencephalogram [EEG]) time-locked to some definable event. The magnitude of these changes is small compared with the amplitude of the “background” EEG. ERP waveforms

with satisfactory signal-to-noise ratios are obtained by averaging the EEG samples obtained on a number of trials (typically, 20–50) belonging to the same experimental condition. ERP waveforms thus represent estimates of time-locked neural activity elicited by stimuli belonging to different experimental conditions (see Kutas and Dale, 1998, and Rugg and Coles, 1995a, for introductions to the ERP technique).

ERPs are useful for studying memory for a number of reasons. First, neural activity associated with stimulus processing can be measured with a temporal resolution in the millisecond range. Thus, upper-bound estimates of the time required by the nervous system to discriminate between different classes of item (e.g., old and new words in a recognition memory test) can be made directly. This level of temporal resolution is presently unattainable with functional neuroimaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). A second benefit of the ERP technique, central to the research reviewed subsequently, is that ERP waveforms can be formed “off-line,” after the experimental trials have been sorted into different conditions according to the subject’s behavior. Thus, it is easy to compare records of brain activity associated with different classes of response to the same experimental items (e.g., hits vs. misses, or false alarms vs. correct rejections).

Finally, ERPs can be used to investigate whether different experimental conditions engage functionally dissociable cognitive processes. This application of ERPs rests on the assumption that if two experimental conditions are associated with qualitatively different patterns of scalp electrical activity, this usually signifies the engagement of at least partially nonoverlapping neural and, thus, functional processes (Rugg and Coles, 1995b). In the following research, the analysis of the spatial distribution (the “scalp topography”) of ERP effects occupies a central place; when two topographies differ, we take this to mean that the cognitive processes engaged in the respective experimental conditions are not identical.

Event-related potentials and memory retrieval

Studies employing ERPs to investigate memory retrieval have shared a common logic. Event-related potential waveforms are obtained during memory tests for two or more classes of test item. Items may be defined *a priori* (e.g., previously studied vs. unstudied) or classified according to behavior (e.g., recognition hit vs. false alarm). Differences between the ERPs elicited by different classes of test items are taken to represent the neural correlates of the memory processes engaged to a greater extent by one class of item than another.

Theoretical background

There have been numerous proposals about how memory for specific events is fractionated. Perhaps the most widely accepted fractionation is between explicit (aware) and implicit (unaware) memory. This distinction is supported by findings (see Moscovitch, Vriezen, and Gottstein, 1993, for review) demonstrating that implicit memory, as assessed by performance on “indirect” memory tests (when memory for study items is incidental to task performance and expressed through “priming” effects such as facilitation of reaction time or identification accuracy), can be normal or near normal in amnesic patients exhibiting severe impairments on the “direct” memory tests of recognition and recall. The distinction receives further support from the many studies with healthy participants in which dissociations between direct and indirect test performance have been reported (see Roediger and McDermott, 1993, for review). Findings from neuropsychological and normal studies suggest that implicit memory may further fractionate into “data-driven” and “conceptually-driven” components (Roediger and McDermott, 1993). Data-driven implicit memory reflects processing overlap at early, presemantic processing stages, as evidenced by its relative insensitivity to the degree of semantic processing accorded study items and its sensitivity to the perceptual similarity of study and test items. Conceptually-driven implicit memory is a consequence of processing overlap at the semantic level and shows the reverse pattern of sensitivity to semantic and perceptual variables.

A second and more controversial memory fractionation is between two different forms of explicit memory—familiarity and recollection (episodic retrieval). According to the proponents of “dual process” models (Jacoby and Dallas, 1981; Jacoby and Kelley, 1992; Mandler, 1980; Richardson-Klavehn, Gardiner, and Java, 1996), these two forms of memory represent qualitatively different ways in which a retrieval cue can ac-

cess information about a past episode. In the case of recollection, the information includes contextual details of the learning episode and is accompanied by the phenomenological experience of having brought back to mind (“remembering”) a specific past event. When memory is based on familiarity, information about the context in which the test item was encoded, and the phenomenal experience of remembering (in the sense defined previously) are both absent.

Event-related potentials and implicit memory

As has been noted previously (Rugg 1995a, b), the identification of an electrophysiological correlate of implicit memory requires more than the mere demonstration that ERPs vary in an indirect memory test according to the study status of the items (e.g., old vs. new). It also is necessary to show that the ERP effect does not reflect “incidental” or “involuntary” explicit memory (Bowers and Schacter, 1990). Because of the difficulty of satisfying this requirement, one of us (Rugg, 1995a, b) argued that despite the large number of studies demonstrating the sensitivity of ERPs to item repetition in indirect memory tests, it was not possible to conclude that any aspect of these “ERP repetition effects” reflected implicit memory. One way around this impasse is to employ experimental manipulations known to have dissociative effects on implicit and explicit memory. The demonstration that an ERP memory effect is modulated by the same variables that selectively influence behavioral manifestations of implicit memory makes it unlikely that the effect is a reflection of explicit memory for the test items.

One such variable is presentation modality. As assessed on a variety of indirect tasks, implicit memory is weaker when study and test items are presented in different sensory modalities than when the modality is held constant (Roediger and McDermott, 1993). Therefore, it is noteworthy that the effects of repetition within modality (visual–visual) and across modality (auditory–visual) on ERPs elicited by visually presented words differ markedly (Rugg and Nieto-Vegas, unpublished data; figure 56.1). Although visual–visual repetition gave rise to the “standard” ERP repetition effect—a widespread, positive-going shift that onsets approximately 250 ms poststimulus—auditory–visual repetition resulted in the absence of the early part of this effect. As illustrated in figures 56.1 and 56.2 (see color plate 37) even when repetition was immediate, within- and across-modality repetition effects differed in their magnitudes and scalp topographies.

These findings point to the existence of neural activity occupying a latency region of approximately 200 to

FIGURE 56.1 Event-related potentials (ERPs) from Rugg and Nieto-Vegas (unpublished data), illustrating the effects of immediate word repetition within and across modality on ERPs to visually presented words. ERPs are shown from mid-frontal

(Fz), mid-central (Cz), and mid-parietal (Pz) electrodes. The task requirement was to respond to occasional animal name “targets.” Modality-dependent repetition effects are prominent from approximately 200 to 400 ms poststimulus.

400 ms poststimulus that is both repetition and modality sensitive. This effect seems likely to reflect the modulation of perceptual processes contributing to data-driven implicit memory for words and word-like stimuli. This proposal receives support from the finding (Doyle, Rugg, and Wells, 1997) that “formal” priming (e.g., SCAN-SCANDAL), nonword repetition (e.g., BLINT-BLINT), and word repetition all have similar effects on ERPs in the latency range occupied by the modality-sensitive effects illustrated in figure 56.1. Event-related potential findings analogous to those of Rugg and Nieto-Vegas (unpublished data) were also described by Paller and associates (Paller, Kutas, and McIsaac, 1998; Paller and Gross, 1998), who employed manipulations of item presentation format, rather than modality, to identify ERP correlates of data-driven implicit memory. In sum, these observations suggest that ERP repetition effects may reflect the functioning of the domain-specific “perceptual representation systems” proposed by Tulving and Schacter (Tulving and Schacter, 1990; Schacter, 1994) to underlie data-driven priming.

The neural correlates of implicit memory can also be investigated in direct memory tests by contrasting ERPs elicited by studied items that are misclassified as new (misses) with those elicited by correctly classified new items. On the assumption that studied items are “missed” when they fail to elicit explicit memory, differences between these two classes of ERPs represent neural correlates of implicit memory retrieval. This approach has two advantages over studies that investigate implicit memory with indirect memory tests. First, the problem of “contamination” by explicit memory is minimal; the critical items are those that were not remembered explicitly at the time the ERPs were recorded. Second, the approach allows the neural correlates of implicit and explicit memory to be contrasted in one and the same test. This is important because almost all studies that have sought to dissociate brain activity associated with implicit and explicit memory have contrasted findings from direct and indirect tests. Because memory retrieval is intentional on direct tests but unintentional on indirect tests, such

Within Modality (200-400 msec)

Across Modality (400-600 msec)

effects. Right panel: distribution of the late (400–600 ms) across modality effects. The latter effects have the more posterior distribution.

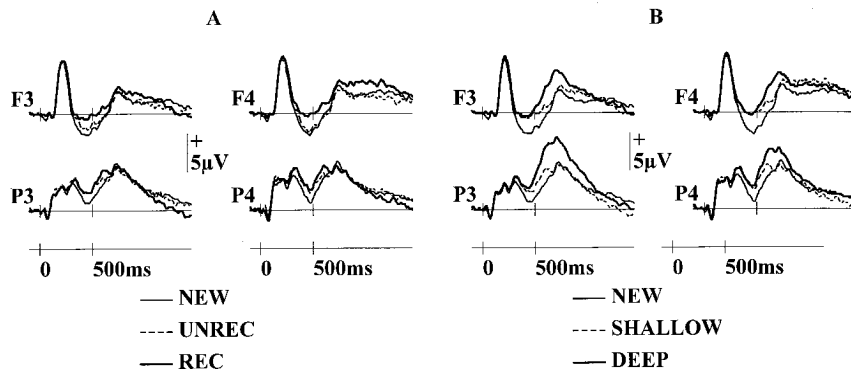

FIGURE 56.3 Event-related potentials (ERPs) from Rugg and associates (1998b), shown for lateral frontal (F3, F4) and parietal (P3, P4) sites. (A) Waveforms elicited by correctly rejected new items (new), and by recognized (rec) and unrecognized (unrec) old items. Note the similarity at the parietal sites of the

early differences between the ERPs to new items and those to each class of old item. (B) Waveforms elicited by correctly rejected new items, and recognized items accorded either deep or shallow study.

studies confound retrieval intentionality with type of memory.

Event-related potentials elicited by recognition “misses” were investigated by Rugg, Mark, and colleagues (1998). Participants studied a series of words under either “deep” (sentence generation) or “shallow” (alphabetic judgment) conditions and subsequently were tested for their recognition memory of these words. Although more than 90% of the deeply studied words were recognized, this was true for only 50% of the shallowly studied items, permitting ERPs of equivalent signal quality to be formed for shallow “hits” and shallow “misses.” At central and parietal electrode locations, the ERPs to

hits and misses were both more positive-going than were those to correct rejections. At frontal sites, by contrast, only the ERPs to hits differed from those to new items (figure 56.3A). Furthermore, as shown in figure 56.3B, up to approximately 500 ms poststimulus, a very similar ERP modulation was found in the ERPs from parietal electrodes that were elicited by deeply studied test items. Thus, “shallow misses,” “shallow hits,” and “deep hits” were all associated with a posteriorly distributed positive-going memory effect between approximately 300 to 500 ms poststimulus.

These findings suggest that ERPs detect neural activity associated with implicit memory for recently experi-

**Shallow Hit - New

FIGURE 56.4 Topographic maps of the differences between the ERPs to old and new words shown in figure 56.2, showing the distribution of the differences between 300 and 500 ms for

recognized (hit) and unrecognized (miss) words, and between 500 and 800 ms for recognized deeply studied words.

enced words and that this activity is neuroanatomically dissociable from that associated with explicit memory (figure 56.4; see color plate 38). Thus, when task factors are held constant, these two forms of memory nonetheless can be dissociated neurophysiologically.

In summary, the view (Rugg, 1995a, b) that there are no convincing examples of ERP correlates of implicit memory no longer seems tenable. Event-related potential repetition effects in indirect tasks are sensitive to the degree of perceptual match between study and test items, mimicking the sensitivity of data-driven implicit memory to this variable. Furthermore, there is evidence that ERPs detect neural activity that is sensitive to the repetition of items for which recognition failed. An important remaining question is whether these different putative neural correlates of implicit memory reflect the activity of a common neural population.

Recollection versus familiarity

As already noted, the proposal that two functionally distinct forms of memory—recollection and familiarity—support recognition memory is controversial. Although support for this view has been claimed on the basis of behavioral findings from studies of both healthy (Jacoby, 1991; Jacoby and Dallas, 1981; Yonelinas, 1994) and amnesic (Verfaillie and Treadwell, 1993) participants, the claims have been challenged on the grounds that the findings can be accommodated within models of recognition memory that posit only a single process (Knowlton and Squire, 1995; Mulligan and Hirshman, 1997).

The question of whether recognition memory is supported by one or two processes has been addressed in a number of ERP studies, employing a variety of operational definitions of familiarity and recollection. In all

FIGURE 56.5 Data from Wilding and Rugg (1996, expt. 2) illustrating ERPs from lateral frontal and parietal electrodes elicited during a source memory test by words correctly classified as new (correct rejections), recognized and assigned to the incorrect study context (hit-miss), or recognized and assigned to the correct study context (hit-hit).

studies, test items were segregated according to whether they were recollected or recognized on the basis of familiarity alone. If ERP memory effects (i.e., the differences between ERPs to recognized and to new items) elicited by the two classes of item are topographically distinct, this would lend support to the view that recollection and familiarity are supported by functionally distinct cognitive operations. By contrast, single-process models would receive support from the finding that differences between the memory effects are quantitative only.

One way to operationalize the distinction between recollection and familiarity is with a test of source memory. In such tests, participants study a series of items in one context or another. At test, they discriminate studied from unstudied items (yes/no recognition), and in addition, they categorize recognized items according to their study context. According to proponents of the dual-process framework (Jacoby, 1991), trials on which source memory is successful involve recollection of the study episode, whereas trials on which recognition is accurate but memory for source is not are likely to be based solely on familiarity. Thus, the relative proportions of trials associated with each form of memory should vary according to whether source memory is successful or unsuccessful. If recollection and familiarity have distinct neural correlates, the scalp distributions of ERPs elicited by recognized items should vary according to the accuracy of the source judgment.

Wilding and colleagues reported two studies in which ERPs associated with accurate and inaccurate source

FIGURE 56.6 Event-related potentials (ERPs) from lateral frontal and parietal electrodes from the associative recognition task of Donaldson and Rugg (1998, expt.1). New = correctly rejected new pairs; Same = word pairs that maintained their pairing between study and test and that were classified correctly as such; Rearranged = word pairs that were rearranged between study and test and correctly classified as such.

memory were contrasted. In their first study (Wilding, Doyle, and Rugg, 1995), the source attribute was sensory modality; in the second study (Wilding and Rugg, 1996), it was speaker voice. In both cases, memory effects were larger for recognized items that were assigned correctly to their study context, but in neither case was there evidence that the effects differed qualitatively (figure 56.5).

Similar findings were reported by Donaldson and Rugg (1998), who investigated the ERP correlates of associative recognition. Participants performed recognition judgments on word pairs that were new, representations of pairs studied in a preceding study task, or re-pairings of study items. Donaldson and Rugg assumed that words that maintained their pairing between study and test (*same* pairs) would be more likely to elicit recollection than rearranged pairs, a high proportion of which would be recognized exclusively on the basis of familiarity (Yonelinas, 1997). As illustrated in figure 56.6, ERP memory effects were markedly larger when elicited by same versus rearranged pairs. However, there was no evidence that the effects elicited by the rearranged pairs differed qualitatively from those elicited by the same pairs.

The findings reviewed previously (see also Wilding and Rugg, 1997) offer little support for dual process models of recognition memory. Rather, the findings support the view (Johnson, Hashtroudi, and Lindsay, 1993; Mulligan and Hirshman, 1997) that recognition based on “familiarity” depends on the same processes as those that support recollection and is better conceived of as impoverished recollection rather than an independent

FIGURE 56.7 Topographic maps illustrating the scalp distribution of the differences between ERPs elicited by “recollected” words and words correctly classified as new for three consecutive regions of the waveforms (500–800, 800–1100, 1100–1400 ms poststimulus). Maxima corresponding to the left parietal

basis for recognition. This conclusion is tempered by the possibility that these negative findings reflect the insensitivity of ERPs to the neural activity supporting familiarity, rather than the inadequacy of dual-process models.

The foregoing conclusion also should be qualified in light of the findings from two studies in which a dissociation between the neural correlates of recollection and familiarity may have been obtained. Düzel and colleagues (1997) employed the “Remember/Know” procedure (Tulving, 1985) to distinguish between trials on which recognition was associated with the presence or absence of a “recollective experience.” Düzel and associates (1997) reported that ERPs elicited by recognized words endorsed as remembered or known differed in their scalp distributions from approximately 300 to 1000 ms poststimulus. These findings suggest that recollection and familiarity indeed may be electrophysiologically dissociable. For two reasons, however, this conclusion should be considered tentative. First, the number of trials forming the ERPs to old words assigned a “know” judgment was very low in some participants, raising concerns about signal quality. Second, the claim of differing scalp topographies for the ERPs associated with remember and know judgments was made in the absence of appropriate statistical analysis (McCarthy and Wood, 1985).

The second study to suggest that familiarity and recollection can be dissociated electrophysiologically is that of Rugg, Mark, and coworkers (1998) described in the previous section. As shown in figure 56.3, between approximately 300 and 500 ms poststimulus, ERPs from frontal electrodes were more positive-going for recognized old words than they were for correctly rejected and missed items. Unlike the prominent memory effects

and right frontal effects are clearly evident. The ERPs to recollected items were elicited by words that were either correctly recognized and assigned to their study context, or recognized and given a “remember” judgment in a “remember/know” task. (Data are from Mark and Rugg, 1998.)

arising after approximately 500 ms, this frontal effect was insensitive to depth of study processing. These findings therefore provide evidence for two qualitatively distinct patterns of neural activity associated with successful recognition, only one of which is sensitive to depth of study processing. If depth of processing exerts its effects exclusively through recollection (Gardiner, Java, and Richardson-Klavehn, 1996), the ERP findings suggest that familiarity and recollection have distinct neural correlates. Unfortunately, it is unlikely that depth of processing does dissociate recollection and familiarity (Toth, 1996; Yonelinas et al., 1998), leaving the interpretation of these ERP findings uncertain.

In summary, recent ERP findings provide, at best, only weak support for dual-process models of recognition memory. It appears, however, that although ERP memory effects may not dissociate two bases for recognition memory, the effects are sensitive to more than just whether a test item is old or new and index instead the amount of information that can be retrieved about the context in which an old item was experienced. Thus, ERP memory effects appear to reflect cognitive operations associated with the recollection of recently experienced episodes (episodic memory). In the next section, we assess this proposal in more detail, and address the question of whether the cognitive operations supporting recollection can be dissociated neurally and functionally.

Event-related potentials and recollection

As is evident from figures 56.5 and 56.7 (see color plate 39), the ERP memory effects associated with successful recollection are manifest as at least two positive-going

modulations of the waveform, dissociable on both temporal and neuroanatomical criteria (see also Allan, Wilding, and Rugg, 1998). One of these modulations (the “left parietal effect”) onsets at approximately 400 to 500 ms, is maximal over the left parietal scalp, and typically has a duration of approximately 500 ms. The other modulation (the “right frontal effect”) onsets at about the same time or a little later, is maximal over the right frontal scalp, and is considerably more sustained over time.

The proposal that the left parietal effect is an electrophysiological correlate of recollection fits well with the findings of previous research investigating the ERP correlates of recognition memory (Rugg, 1995a,b; Allan, Wilding, and Rugg, 1998). The proposal receives additional support from studies (Düzel et al., 1997; Johnson et al., 1997) in which the ERP correlates of “false recollection” (Roediger and McDermott, 1995) were investigated. This term refers to the tendency of participants to make a “false alarm” response to unstudied associates of study items and to endorse such responses as “remembered.” This tendency is believed to depend on the same processes that support “true” recollection (Schacter et al., 1996). Düzel and associates (1997) and Johnson and colleagues (1997) found that in contrast to the ERPs elicited by false alarms to items that are not associates of study words, the ERPs to falsely recollected items elicited prominent left parietal effects, comparable in magnitude to the effects elicited by items correctly endorsed as old.

The right frontal effect appears to be most prominent in tasks that require more than simple old/new recognition judgments and first came to light in the study of source memory by Wilding and Rugg (1996; see figure 56.5). The effect was also found in the associative recognition task of Donaldson and Rugg (1998; see figure 56.6), in the Remember/Know task (Rugg, Schloerscheidt, and Mark, 1998; Düzel et al., 1997) and, in a much attenuated form, in a study of old/new recognition (Allan and Rugg, 1997a).

The differing spatiotemporal characteristics of the left parietal and right frontal effects suggest that they reflect distinct cognitive operations. Wilding and Rugg (1996) proposed that these operations involve the retrieval of item and contextual information from memory—operations supported by the “medial temporal lobe memory system” (Squire, 1992)—and processing the products of retrieval to generate an episodic representation capable of supporting accurate source discrimination—operations held to be dependent on the prefrontal cortex (Squire, Knowlton, and Musen, 1993). Wilding and Rugg (1996) linked the left parietal effect to the first of these operations and the right frontal effect with the second, “post-retrieval,” operation.

By linking the left parietal effect to retrieval operations supported by the medial temporal lobe, Wilding and Rugg (1996) did not mean to imply that the effect directly reflected neural activity in these regions. Indeed, current evidence suggests that hippocampal activity makes, at best, a very modest contribution to scalp-recorded potentials (Rugg, 1995c). A more likely possibility is that the left parietal effect reflects changes in cortical activity resulting from the corticohippocampal interactions that have been proposed to underlie episodic memory retrieval (McClelland, McNaughton, and O’Reilly, 1995). This hypothesis about the neural origins of the left parietal effect is consistent with the findings of a PET study of depth of processing effects on recognition memory (Rugg et al., 1997; Rugg, Walla, et al., 1998). Relative to the recognition of shallowly studied items, recognition of deeply studied items was associated with activation not only in the left hippocampal formation, but also in an extensive region of the cortex of the left hemisphere, including frontal, temporal, and parietal areas.

The proposal that the right frontal effect reflects cognitive operations associated with “post-retrieval” processing receives support from both functional and neuroanatomical evidence. The idea that the products of memory retrieval are subjected to such operations as “monitoring” or “evaluation,” and that the need for such operations varies with task demands, is central to some models of memory retrieval (Koriat and Goldsmith, 1996). The nature of the memory impairments that follow lesions of the prefrontal cortex suggests that these impairments reflect, in part, the disruption of post-retrieval processing (Shallice, 1988).

The scalp distribution (figure 56.7) of the right frontal effect suggests that its generator is located within right prefrontal cortex. This hypothesis receives support from the findings of studies of memory retrieval using PET and fMRI, which have demonstrated consistently that episodic memory retrieval is associated with activation of right dorsolateral and anterior prefrontal cortex (Fletcher, Frith, and Rugg, 1997). The hypothesis receives further support from functional neuroimaging studies showing that the activity of this region is greater when recognition memory test items elicit successful retrieval than when they do not (Buckner et al., 1998a; Rugg et al., 1996; Rugg, Fletcher, et al., 1998; but see also Buckner et al., 1998b; Kapur et al., 1995; Nyberg et al., 1995).

Thus far, the experiments described in this section have all investigated the ERP correlates of recollection by employing “copy” cues to elicit the retrieval of episodic memories. It is, of course, also possible to elicit memory retrieval with cues that provide only an incomplete specification of study items. One such task is word-stem cued recall, in the simplest version of which partic-

ipants are required to retrieve study words in response to three letter (stem) cues (e.g., MOTEL > MOT___). The ERP correlates of recollection engendered by such cues differ from those found with copy cues (Allan, Doyle, and Rugg, 1996; Allan and Rugg, 1997a, b). These studies all employed the same basic test procedure: A series of stems were presented, only a proportion of which corresponded to study items. Participants attempted to retrieve a study word in response to each stem and, following a response cue, provided a study word if they could or gave the first word to come to mind. Crucially, participants also judged whether each completion belonged to the study list, making it possible to separate recalled study items according to whether recall was implicit (associated with the judgment that the item had *not* appeared at study) or accompanied by explicit memory for the study presentation (associated with a positive judgment; see Jacoby, Toth, and Yonelinas, 1993, and Jacoby, 1998, for discussion of the explicit/implicit distinction in cued recall).

The basic finding from these studies is illustrated in figure 56.8, which contrasts waveforms elicited by stems completed with explicitly retrieved study words and unstudied items. The ERPs to the stems corresponding to the studied items show a positive-going ERP modulation that onsets at approximately 300 ms and continues until the end of the recording epoch. Figure 56.9 (see color plate 40) shows that the scalp distribution of these memory effects evolves from an initial anterior midline focus to include a left temporoparietal maximum, before shifting back to a (right) anterior focus. These effects seem likely to be a relatively pure reflection of episodic memory because they are absent in ERPs elicited by stems completed with falsely recognized unstudied items and in ERPs elicited by correct completions wrongly judged

FIGURE 56.8 Event-related potentials (ERPs) from lateral frontal and parietal electrodes elicited by word stems in the study of Allan and Rugg (1997b). ERPs are shown for stems correctly completed with items judged to have been shown at study, collapsed across a subsequent source (study list) judgment (recalled), and for stems completed with unstudied items correctly endorsed as “new” (new completion).

to be unstudied (Allan, Doyle, and Rugg, 1996). This proposal is strengthened by the findings of Allan and Rugg (1997b). Employing a source procedure, they reported that the scalp distribution of the memory effects for correctly completed stems assigned to their correct encoding context was indistinguishable from the distribution of the effects elicited by stems attracting an incorrect source judgment. This finding suggests that, as far as can be detected from the scalp, the same memory processes supported retrieval of the study item and its encoding context.

The findings from the cued recall studies described previously are important for two reasons. First, they

FIGURE 56.9 Topographic maps illustrating the scalp distribution of the memory effects shown in figure 56.8. Each map depicts the differences between ERPs evoked by stems correctly completed with studied items, collapsed across the subsequent

source judgment, and ERPs evoked by stems completed with unstudied items correctly endorsed as “new.” Maps are shown for three latency regions, 400–700 ms, 800–1100 ms, and 1200–1500 ms.

indicate that recollection is associated with more than one pattern of ERP memory effects. Although the effects from cued recall appear to include contributions from the generators of the left parietal and right frontal effects discussed previously, the cued recall effects are distributed more diffusely over the scalp than are the effects elicited by copy cues (Allan and Rugg, 1997a). Second, the findings show that the left parietal effect is not necessarily the earliest electrophysiological sign of successful memory retrieval. In cued recall, the earliest such sign takes the form of a bilaterally distributed effect over the frontal scalp (figure 56.9). Similar findings have been reported in other studies (figure 56.4; Rugg, Mark, et al., 1998; Tendolkar, Doyle, and Rugg, 1997; Schloerscheidt and Rugg, 1997).

Together, the findings reviewed in this section indicate that recollection—the bringing to mind of aspects of a prior episode—is associated with a pattern of neural activity that varies in its scalp distribution over the first two seconds or so following the presentation of a retrieval cue. Although part of this activity (e.g., that reflected by the left parietal effect) appears to be engaged in an obligatory fashion when a test item engenders recollection, other activity appears to be more task dependent.

By identifying the structures responsible for generating recollection-related ERP effects and specifying their functional significance, it will be possible to shed further light on the mechanisms by which retrieval cues engender recollection and the means by which representations of prior experiences can be used to guide behavior.

57 Neuroimaging of Memory

RANDY L. BUCKNER

ABSTRACT Human functional neuroimaging based on positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) provides a powerful means of linking neural level description of brain function and memory. In this chapter, the bases of these neuroimaging methods are discussed, along with three distinct sets of findings linking memory-related cognitive processes to brain activity. (1) Memory encoding activates specific posterior prefrontal regions (near Brodmann areas 44/6 and 44/45) that act interdependently with medial temporal regions to promote memory formation. The laterality of activity within these regions is modulated by the kinds of materials being memorized; verbal materials almost always have activated left-lateralized cortex and nonverbal materials have activated either left- or right-lateralized cortex, depending on the specific encoding task. (2) Repetition of items that results in priming is accompanied by activity reductions in brain areas activated during a task. These reductions can be found in both perceptual and higher-level brain areas, depending on which task components are facilitated through repetition. (3) Explicit attempts to remember the past are associated with increases in anterior prefrontal activity (near Brodmann area 10) that generalize across stimulus type and exact test format. Such investigations suggest that anterior prefrontal areas may participate in processes associated with monitoring of the retrieval attempt. Taken collectively, these three sets of findings illustrate how neuroimaging methods can be applied to elucidate questions about human memory, complementing and extending data derived from other methods.

A primary challenge for the cognitive neuroscience of human memory is the development and application of methods that link mnemonic processes with their underlying neural bases. Providing one kind of link, functional neuroimaging methods offer a means to visualize brain areas active during cognitive operations in awake, healthy humans. By monitoring changes in blood properties correlated with neuronal activity, these methods enable measurement of localized changes in brain function (Posner and Raichle, 1994). In their most technically refined forms, these methods presently allow noninvasive imaging of single trials in memory tasks with a spatial resolution of a few millimeters. This chapter focuses on these and other aspects of how functional neuroimaging methods are

being applied to the study of human memory. The basic properties and limitations of commonly used methods are presented, followed by a description of recent findings.

What can neuroimaging methods tell us about memory?

Cognitive neuroscientific inquiry into human memory seeks to understand how brain activity is modified by experience and to further understand how these modifications influence future information processing. In non-human primates and other animals, single-unit activity of neurons or populations of neurons can be recorded directly. In humans, however, these procedures are too invasive to perform other than in the context of brain surgery. We must, therefore, seek alternative methods to characterize neuronal changes relating to memory.

Functional neuroimaging techniques (PET and fMRI) provide one set of alternatives and are able to measure indirectly net neuronal changes within the human brain (Posner and Raichle, 1994; Roland, 1993). PET and fMRI both take advantage of a fortuitous physiologic property: When a region of the brain increases activity, blood flow to that region increases. By injecting into the blood stream radiolabeled isotopes that can be detected by PET scanners, PET allows visualization of blood flow changes relating to neural activity. Functional MRI, which has been applied only widely in the past 5 years, similarly visualizes neural activity indirectly through blood property changes that affect the magnetic signal to which MRI images are sensitive (Kwong et al., 1992).

Several empirical observations suggest that the signals detected by PET and fMRI are valid measurements of local changes in neuronal activity. First, studies of visual cortex activation in relation to well-understood retinotopic organization have repeatedly demonstrated predictable activation patterns (Fox et al., 1995; DeYoe et al., 1996; Sereno et al., 1995) and suggest a current practical resolution of approximately 3 to 6 mm (Engel et al., 1997). Resolution at this level can map areas within broad regions of cortex, such as separate areas within prefrontal or occipital cortex, or can distinguish between

RANDY L. BUCKNER Departments of Psychology, Anatomy and Neurobiology, and Radiology, Washington University, St. Louis, Mo.

the amygdala and hippocampal formation, but would not be expected to resolve the columnar organization within a functional area. Second, fMRI signal change tracks neuronal activity temporally. When prolonged or multiple visual stimuli have been presented to subjects, the fMRI signal summates across the separate (Dale and Buckner, 1997) and continuous (Boynton et al., 1996) evoked neuronal events, as would be predicted for a measurement linked to neuronal activity. Neuroimaging methods also have demonstrated reliability across independent subject groups and even imaging modality (e.g., PET compared with fMRI; Ojemann et al., 1998; Clark et al., 1996). However, despite their many advantages, these methods do come with limitations.

It is unlikely that PET or currently applied fMRI provides much information about local physiologic properties (e.g., whether net activity changes reflect inhibitory or excitatory synapses, or the relative combinations of the two). In this regard, studies with current functional neuroimaging methods likely yield information about net changes in activity (both excitatory and inhibitory) within brain regions spanning several millimeters of the cortex. Furthermore, changes in blood flow in response to neuronal activity are revealed on a temporal scale far longer than the neuronal activity itself (Raichle, 1987; Rosen, Buckner, and Dale, 1998); for a brief sensory event lasting fractions of a second, blood properties change over a 10- to 12-s period. This temporal “blurring” of the signal provides a limitation, but perhaps not as severe as one might imagine. For example, changes in neural activity associated with individual trials of a task can be observed (Buckner et al., 1996). Richter and associates (1997), in a dramatic demonstration of fMRI temporal resolution and sensitivity, captured brain activity associated with a single momentary cognitive act of mentally rotating a stimulus, without averaging over events. Functional MRI methods also have taken advantage of the reliable timing of the evoked blood flow signal to demonstrate temporal resolution at the subsecond level (Menon et al., 1998; Rosen, Buckner, and Dale, 1998).

Beyond basic technical considerations, one also must consider issues related to the practical application of neuroimaging techniques to questions about higher human brain function. Namely, how can a set of tasks and the trials within the tasks be constructed to disentangle brain-based cognitive operations? The basic paradigm construct most commonly used is to have subjects engage one task for a period of time (perhaps a verbal memory retrieval task) and then contrast that with periods of time where subjects perform a reference task (perhaps a matched task involving many of the same components, but lacking a memory retrieval demand).

The logic of such a paradigm assumes that brain activity changes between the two task states and correlates selectively with the manipulated memory retrieval demands. More recently, paradigms that isolate individual trials of memory tasks have been developed—so-called “event-related” procedures (Rosen, Buckner, and Dale, 1998). These procedures allow experimenters to contrast activity associated with different trial types, much like electroencephalogram (EEG) and magnetoencephalogram (MEG) data are analyzed (see chapter 56).

Within both of these paradigm constructs, a significant challenge arises from the uncertainty surrounding how to design tasks that can isolate component processes involved with memory. Although no sure answer can be given here, two basic points are worth making. First, because there is uncertainty, no single study reveals a complete picture. Commonalties across groups of studies should be used to identify convergent findings. Second, it is essential to consider exactly what a subject is performing during the task period or trial being imaged. Memory is an odd entity in this regard. The essence of memory is how task performance at one point in time influences performance at another point in time. Key memory processes associated with storage and learning extend over time. Neuroimaging methods, however, likely only reveal neural correlates of the subset of memory processes associated with acute changes in activity that occur when tasks are being performed. That is, PET and fMRI measurements reflect what a subject is doing at the time of imaging. Such performance may influence learning or benefit from learning, but the snapshot of brain activity provided most likely reflects active information processing associated with task performance and immediate task goals. Memory processes set into motion by the active information processing, but not revealed in terms of acute net changes in neural activity, go undetected. These methods are thus unlike those based on patients with lesions that provide information about processes of any sort that are affected by a loss of a brain region.

Following, three separate areas in which insights about human memory function have been gained through neuroimaging studies are discussed with key points summarized in italics (for additional reviews, see Buckner and Tulving, 1995; Cabeza and Nyberg, 1997; Fletcher, Frith, and Rugg, 1997; Schacter and Buckner, 1998; Ungerleider, 1995).

Episodic memory encoding

A prime example of how neuroimaging has been applied to study human memory arises in explorations of episodic encoding. Memory encoding occurs when in-

formation processing leads to memories (and presumably neuronal changes) that endure over time. Daniel Schacter described encoding as “a special way of paying attention to ongoing events that has a major impact on subsequent memory for them” (Schacter, 1996). These processes may be engaged when subjects *intentionally* attempt to remember new materials or when information processing, by means of the kind of task a subject engages, *incidentally* encourages memorization of new materials (Craik and Lockhart, 1972; Craik and Tulving, 1975). Functional neuroimaging studies suggest that both intentional and incidental episodic encoding may depend on common functional changes in brain activity in prefrontal cortex. The data further suggest that frontally mediated processes may involve strategic and volitional aspects of encoding that act interdependently with medial temporal regions to promote memory formation.

FUNCTIONAL-ANATOMIC CORRELATES OF EPISODIC ENCODING An early illustration of a prototypic incidental encoding study is provided by Kapur and colleagues (1994). In their study, subjects decided whether visually presented words represented entities that were either living or nonliving. This meaning-based (or “deep”) word-processing task led to high incidental encoding as evidenced by 75% correct recognition on a later memory test. Positron-emission tomography imaging data contrasting this deep encoding task to a second, poorer encoding task (57% correct recognition) demonstrated robust activation of multiple prefrontal regions. Of importance, this effect was mediated by subject-initiated strategies. Across all encoding conditions, the same items (by means of counterbalancing) were presented. The goals of the subject across conditions mediated participation of left prefrontal regions and facilitated memory encoding.

This basic finding has been replicated and extended with fMRI. Gabrieli and colleagues (Demb et al., 1995; Gabrieli et al., 1996) and Wagner and associates (1998b) have explored another incidental encoding task using fMRI, in which participants decide whether words are abstract (e.g., hope) or concrete (e.g., tree). Significant left prefrontal activation was noted in each of these studies. Demb and associates (1995) further demonstrated that prefrontal activity changes are selective to the kinds of processes that promote encoding and not due to secondary factors such as task difficulty or time on task. In their study, subjects made a difficult surface judgment about the words that took longer to complete than the meaning-based “deep” encoding task. Despite the longer time to respond, minimal activity change was noted for left prefrontal cortex and memory performance was poor. Furthermore, *intentional* memorization

FIGURE 57.1 One example of the association between posterior prefrontal cortex activity and memory encoding is displayed (adapted from Wagner et al., 1998b). The graph shows an fMRI signal change for a left prefrontal region during a verbal semantic classification task. The signal is shown separately for those words later remembered versus those words later forgotten. A clear difference is apparent: Increased activity predicts whether the word will be remembered or forgotten, suggesting a link between processing within left prefrontal cortex and effective verbal memory encoding.

of verbal materials has activated similar left prefrontal regions (Kapur et al., 1996; Kelley et al., 1998), suggesting, as would be predicted from behavioral studies (Craik and Tulving, 1975), that both kinds of encoding task lead to engagement of common underlying processes and brain systems.

Illustrating the variety of manners in which neuroimaging studies may be conducted, procedures for sorting fMRI data post hoc based on subject performance provide yet another link between processing associated with left prefrontal cortex and long-term memory encoding. Using event-related fMRI, Wagner and colleagues (1998b) sorted words presented during a deep encoding task by whether the words were remembered subsequently or forgotten on a later recognition test (similar to many event-related potential (ERP) studies; Halgren and Smith, 1987; Paller, 1990). Left prefrontal regions hypothesized to be involved in memory encoding via direct manipulations of encoding operations (Kapur et al., 1996) were most active for those words that would be subsequently remembered (figure 57.1). In essence, neuroimaging measurements of specific left prefrontal brain regions could predict—on average—the level of encoding associated with individual words. The conclusion across all these neuroimaging studies is that *the left prefrontal cortex is active when subjects engage verbal processing tasks that lead to encoding*. Figure 57.2 illustrates this convergence.

It is not, however, likely that left prefrontal regions participate exclusively to promote memory encoding. Quite to the contrary, it appears more reasonable that

FIGURE 57.2 A schematic of the left hemisphere shows convergence across a number of studies in which verbal episodic memory encoding has been examined (shaded region). Multiple distinct regions of the posterior left prefrontal cortex are consistently active during verbal memory encoding.

their processing contributions surround active verbal (and perhaps certain forms of nonverbal) information processing that can, as a byproduct, yield activity changes that result in enduring memories. A number of data support this position. Many verbal processing tasks that occur without any instruction to form new memories (or even in the context of a memory study) activate these left prefrontal regions, as noted for several of the aforementioned studies. These kinds of tasks incidentally promote memorization of the words encountered (Tulving et al., 1994). Similarly, a number of verbal working memory tasks have activated these left prefrontal regions (for reviews, see Smith and Jonides, 1997). At the farthest extreme, direct comparisons between intentional verbal encoding and verbal tasks designed to isolate memory retrieval processes have produced similar left prefrontal activations (Buckner and Koutstaal, 1998). The inevitable conclusion is that elaborate verbal processing in a broad range of contexts can activate multiple regions in inferior and dorsal prefrontal cortex and promote memory encoding. This may be the neural basis of “deep” encoding. *Certain forms of elaborate information processing engaged to solve task demands in the present use left prefrontal regions and, as a byproduct, set into motion the cascade of events that leads to memory formation.*

HEMISPHERIC ASYMMETRIES A debated topic has been whether the left prefrontal cortex is associated broadly with processing changes related to episodic encoding or for only a subset of operations relating to verbal materials. On one side of the debate, neuropsychological findings often have found asymmetries in relation to the kinds of materials being processed, the left hemisphere associated more with verbal materials and the right with nonverbal materials. Although such ideas provide only heuristic distinctions, they nonetheless predict against a

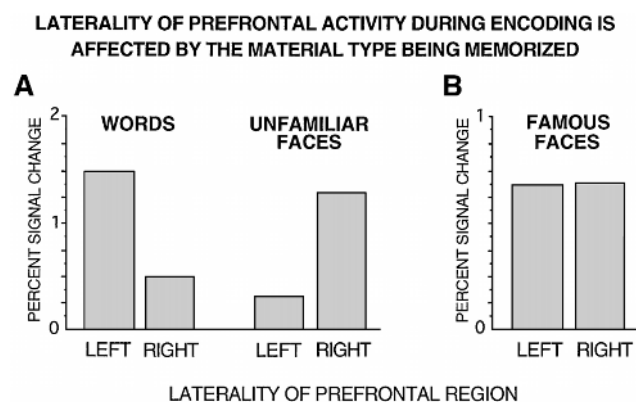

FIGURE 57.3 Data from Kelley and colleagues (1998a, b) demonstrate that lateralization of posterior prefrontal cortex activity during episodic memory encoding can be influenced by the kind of materials being memorized. (A) In their study, verbal materials (words) activated left prefrontal cortex while nonverbal materials (unfamiliar faces) activated right prefrontal cortex (but see also Grady et al., 1995; Haxby et al., 1996). (B) Left prefrontal participation in encoding can be manipulated by increasing the verbal content associated with a stimulus, as shown by the increase in left prefrontal activity when famous faces (e.g., Bill Clinton) are presented, which allow for a verbal referent.

general left-lateralized set of regions for all memory-encoding operations. On the other side, initial neuroimaging studies found almost exclusively left greater than right activity in relation to memory encoding. Based on these neuroimaging data, Tulving and colleagues (1994) formulated an influential model about hemispheric asymmetry in relation to memory function. As part of their model, they postulated that left prefrontal regions are involved in encoding information to the extent that right prefrontal regions are not, at least in so far as verbal information is concerned. The eight initial studies on which they based their model all involved encoding of verbal materials. An open question has been whether left prefrontal regions participating in encoding would generalize to all nonverbal materials or whether neuropsychological findings would predict hemispheric lateralization.

Recent fMRI data suggest that the materials being memorized influence the laterality of the prefrontal areas engaged during encoding. Supporting this possibility, Kelley and associates (1998a) showed that intentional memorization of words activates the left prefrontal cortex whereas memorization of unfamiliar faces (which lack a verbal referent) activates a homologous right frontal region with minimal left frontal activity (figure 57.3). In a further study (Kelly et al., 1998b), they showed that adding a verbal tag associated with the faces additionally activates the left prefrontal cortex in a region similar to that activated by words. This latter finding was demonstrated by contrasting encoding of

nameable famous faces (e.g., Bill Clinton) with unfamiliar faces. Unfamiliar faces activated the unilateral right frontal cortex, whereas nameable famous faces activated the bilateral frontal cortex. The complete interpretation of these findings is complicated by additional studies that have shown bilateral or left-lateralized changes associated with face encoding (Grady et al., 1995; Haxby et al., 1996). However, the presence of studies in which right-lateralized prefrontal regions are sufficient for effective memory encoding argues strongly against the idea that a general encoding operation can be performed only by the left prefrontal cortex. It is more likely that *multiple left and right prefrontal regions participate in memory encoding dependent on the exact materials and/or encoding strategies that certain classes of materials may tend to encourage*. Prefrontal participation in episodic memory encoding appears to be domain specific.

MEDIAL TEMPORAL CONTRIBUTIONS TO MEMORY ENCODING As is well established from human lesion and primate studies, the integrity of the medial temporal lobe is important for the long-term formation of certain kinds of memories (Cohen and Eichenbaum, 1993; Corkin, 1984; Squire, 1992). A puzzle has existed in the neuroimaging field because there have been only sporadic findings of medial temporal lobe involvement in PET and fMRI studies of encoding. Most notably, effective incidental encoding tasks often have failed to detect differential activation in these regions compared with less effective encoding tasks (Buckner and Koutstaal, 1998; Fletcher et al., 1995; Kapur et al., 1994). This has led to past conclusions that functional neuroimaging may be unable to detect reliably the role of medial temporal regions, specifically the hippocampal formation, in memory encoding (Buckner and Koutstaal, 1998; Fletcher, Frith, and Rugg, 1997). However, there also have been several reports of hippocampal involvement in encoding when novel, visual scenes or faces are presented and contrasted with repeated (familiar) stimuli or scrambled meaningless forms (Gabrieli et al., 1997; Grady et al., 1995; Haxby et al., 1996; Stern et al., 1996; Tulving et al., 1996). Across these studies and those that followed, an important (but not completely predictive) variable for activating the hippocampal formation has been the status of the cue (e.g., type, familiarity, and its context). Martin and colleagues (1997), for example, found that the kind of stimulus presented (e.g., word vs. nonsense noise pattern) dictated the level of hippocampal activity. Similarly, Kelley and associates (1998a) noted clear asymmetry of hippocampal formation activation; words activated the left, and faces activated the right. Dolan and Fletcher (1997) found that word pairs differentially

activated the hippocampal formation dependent on the familiarity and prior manner in which they had been associated (paired).

These findings are complicated by several studies yielding null results and a few that have shown modulation of hippocampal formation activity change in relation to task instructions (Kelley et al., 1998a). Nonetheless, the aforementioned studies suggest a reasonably consistent pattern of medial temporal lobe activation, often including the hippocampal formation, when cues are presented that elicit memory encoding. A working hypothesis derived from the neuroimaging data, which is similar to ideas expressed previously based on neuropsychological data (Moscovitch, 1992), is that *strategic frontally mediated processes act interdependently with more cue-driven participation of medial temporal regions to promote memory formation* (see also Schacter et al., 1996; see chapter 56 for a related idea in terms of memory retrieval). Participation of both regions is critical. Task situations that do not activate prefrontal regions tend not to promote long-term memory encoding. Conceptualized in functional terms, the hypothesis is that to encode a memory in a consciously accessible form, it is necessary to involve prefrontal-mediated pathways that participate in high-level representation of the information as well as medial temporal systems that may be necessary for long-term integration or binding of the information (Buckner et al., 1999).

One immediate objection to such an idea may be that frontal lesions often do not significantly impair memory encoding. Here may lie one of the great overstatements of memory research. Left frontal lesions that damage the prefrontal regions commonly activated by memory-encoding tasks cause aphasia and related disturbances of language (Buckner and Tulving, 1995). Contributions that these regions make to memory encoding may have been downplayed previously because of their interdependent roles in active verbal processing and speech production. That is, secondary deficits (e.g., memory encoding) may be overshadowed by their more immediately present symptoms (e.g., production aphasia). Neuroimaging data encourage us to reconsider the important roles prefrontal regions play in episodic memory encoding.

Implicit memory (priming)

Implicit memory refers to any nonconscious influence of past experience on current performance or behavior (Roediger and McDermott, 1993; Schacter, 1987a). Relevant to this chapter, exploration of human neural correlates of implicit memory is an area in which neuroimaging has been influential in providing insight. In particular, a large number of studies have focussed on

A. BEHAVIORAL DATA B. PET DATA FROM VISUAL CORTEX

FIGURE 57.4 Repeating an item within a task leads to decreases in reaction time (A) that correlate with decreases in specific brain areas (B). The change in neural activity in (B) is

likely a correlate of repetition priming. (Adapted from Buckner et al., 1995.)

a subset of implicit memory phenomenon referred to as *priming*. Priming occurs when the ability to identify or produce an item is changed as a result of a specific prior encounter with the item (Tulving and Schacter, 1990). The prototypical experimental task eliciting priming involves presenting items on at least two separate occasions and asking how the presence of the item on the first occasion influences performance measures taken during the presentation of the item on subsequent occasions. Most typically, performance during the repeated exposures is faster or the response is biased (e.g., seeing the word “house” on one occasion speeds the reading of the word “house” on a later occasion).

FUNCTIONAL-ANATOMIC CORRELATES OF PRIMING
Functional-anatomic exploration of priming began with a series of PET studies by Petersen and colleagues (Buckner et al., 1995; Squire et al., 1992) in which subjects were exposed to words (e.g., course) and then asked to generate completions to word-stems (e.g., cou___). Priming was manifest in an increased likelihood that subjects would respond with the study words as compared with the situation where no relevant study words had been presented. Subjects were not instructed to refer to the earlier study lists, yet the primed exposure had implicitly influenced performance. In terms of brain activity, measurements indicated that visual extrastriate regions active during word completion were less active if prior exposure to related words primed performance. Combined with the behavioral observation that primed word completions were produced faster than nonprimed words, the data revealed a neural correlate of priming: *perceptual processing of a stimulus is more efficient after exposure to that stimulus, producing quicker response and requiring less net neural activity in brain areas actively processing perceptual information.*

Activity reductions in extrastriate cortical regions in relation to priming have generalized to a number of different tasks using varied visual stimulus types, including word-stems (Backman et al., 1997; Schacter et al., 1996), word fragments (Blaxton et al., 1996), and visual objects (Buckner et al., 1998a) (figure 57.4). Moreover, examination of the anatomic locations of the priming-related reductions for words and objects indicates that higher-level visual areas are most affected while early visual areas falling at or near the striate cortex are least affected. The data thus suggest that *priming-related activity reductions manifest in an anatomically specific manner, with only a subset of active brain areas modulating in response to prior stimulus exposure* (figure 57.5; Buckner et al., 1998a).

Although anatomic specificity is present, priming-related activity reductions are not limited to perceptual processing areas. Raichle and associates (1994) explored item repetition across a word generation task requiring semantic access. Subjects generated verbs for nouns and then were exposed to many repetitions of the same nouns. They found robust decreases in left prefrontal areas associated with increasing task facilitation across the many item repetitions. Gabrieli and colleagues (Demb et al., 1995; Gabrieli et al., 1996) examined direct-item repetition after a single exposure in a semantic decision task. Subjects viewed words and decided whether the words were abstract or concrete. Functional MRI data revealed that repetition again was correlated with reduced activation in left prefrontal regions. Thus, *priming effects can be observed in higher-order brain regions when appropriate task processes overlap across item repetitions* (Schacter and Buckner, 1998).

Neuroimaging studies of human priming also provide a point of contact for nonhuman primate studies of memory, allowing insight into single-unit neural activity changes that might underlie the PET and fMRI effects

BRAIN AREAS AFFECTED BY PRIMING ARE ANATOMICALLY SELECTIVE

FIGURE 57.5 Priming-related activity reductions are anatomically specific. Functional MRI signal changes across distributed regions of cortex for an object decision task in which items were repeated (primed) or novel. Brain areas within

midlevels of the processing hierarchy (late visual and prefrontal) demonstrate decreased activity in relation to item repetition, whereas earlier visual areas and output motor areas show minimal or no effects of prior item exposure.

(Ungerleider, 1995; Wiggs and Martin, 1998). For example, Miller and Desimone (1994) presented sequences of objects to monkeys, one object at a time. The monkeys' task was to detect a target object identified before the sequence. Secondary to the task, presentation of some of the objects (nontarget objects) was repeated. Net reductions in single-unit activity in the inferotemporal cortex were observed for repeated nontarget objects, similar to repetitions of objects in humans (Buckner et al., 1998a). Moreover, the signal reductions in fMRI and the reductions in single-unit spike activity both rebound (return to near baseline levels) when new items are presented. Thus, the observations in both humans and monkeys suggest item repetition can be associated with a stimulus-specific reduction in activity as would be expected for a neural mechanism underlying behavioral repetition priming effects.

THE CONCEPT OF STIMULUS NOVELTY A number of studies have examined neural correlates of item repetition in the context of asking questions about the fate of novel versus repeated stimuli. These studies suggest the possibility that there exist certain processes to deal with unexpected or novel stimuli (Tulving et al., 1996). Novel stimuli demand the most elaborate and flexible processing because they either are not currently anticipated or do not have a preexisting representation. Critical to this chapter, novelty phenomena share many of the same properties as repetition priming: A differential response is being assessed for novel stimuli compared with repeated stimuli. It therefore is worth flushing out similarities and differences between the two concepts.

The concept of novelty subsumes at least two separable effects. One is the possibility of a signal or a re-

sponse that indicates a stimulus is novel—independent of the specific stimulus. Activity in a population of neurons conveying this kind of “novelty signal” would be expected to modulate during the presentation of a large class of novel stimuli. Such activity could aid in the detection of novelty, but would not participate directly in the perception of the novel object. Another kind of effect would be stimulus specific and manifest as a change in activity in those neurons differentially responsive to the specific stimulus repeating. The former refers to a more global signal that could serve to orient or modulate brain systems, whereas the latter relates to the underlying codes used to identify or process a specific stimulus that may change with experience.

Unfortunately, PET and fMRI data are noncommittal as to which of these two kinds of effect cause the modulations discussed. Visual extrastriate activity reductions, for example, might originate because novel stimuli trigger an enhancement of visual pathways being used to extract visual characteristics of a stimulus independent of the specific stimulus being presented or, alternatively, may reflect decreased (or tuned) activity in neurons coding the specific stimulus in question. The reason for the lack of information is that neuroimaging techniques do not provide information about the responses of specific neurons to specific stimuli. Driven largely by the similarity between human priming-related activity reductions and single-unit studies in monkeys, it seems most likely that the effect is specific to the stimulus and reflects an underlying tuning of cells responsive to novel as compared with repeated stimuli (Desimone et al., 1995).

Miller, Li, and Desimone (1991) suggested, based on single-unit studies, that certain classes of neurons may

“function as adaptive mnemonic ‘filters’ that preferentially pass information about new, unexpected, or not recently seen stimuli.” The same process may be at work in humans and reflect the direct relation between priming and novelty phenomena. When priming is discussed, the immediate effects of neural tuning on performance for items are the focus; when novelty phenomena are discussed, the consequences of the more extensive processing for novel items are the focus, which may include better encoding of the item into long-term memory.

Explicit memory retrieval

Explicit memory, by contrast to implicit memory, is manifest in tasks where there is an intentional attempt to retrieve information from the past. Attempting to remember what one ate for breakfast or where the car is parked are examples of explicit retrieval. In the experimental laboratory, the process of explicit retrieval can be reduced to a study and test procedure in which a subject is instructed during a test to remember words from an earlier study list. To perform such a task, a subject explicitly attempts to remember the past.

FUNCTIONAL-ANATOMIC CORRELATES OF RETRIEVAL ATTEMPT A clear illustration of the presence and effects of explicit retrieval attempt is exemplified in the comparison of two variants of the word-stem completion task. In the implicit variant discussed earlier in this chapter, priming was the focus. Subjects were instructed to complete word-stems with the first word that came to mind. Subjects were not encouraged to retrieve the earlier study words. One can study explicit retrieval attempts by presenting subjects with word-stems, of the same kind used in the implicit tasks, and asking them to use these as cues to recover the words from a specific previously studied list. The goal of the task is changed from generating any word to generating words associated with a specific prior study episode.

With such instructions, two performance changes are evident. First, subjects complete more cues with earlier study words than would be obtained with priming instructions. Thus, *attempting* to retrieve is associated with generating information from the past more readily than would spontaneously occur by way of implicit processes. Second, subjects tend to take longer to complete the word cues. Thus, unlike implicit retrieval processes that tend to have decreased reaction times, explicit retrieval processes tend to have increased reaction times; explicit retrieval attempt has a processing cost.

Correlated with these behavioral changes, functional neuroimaging studies have demonstrated consistently

FIGURE 57.6 Explicitly attempting to remember an item from the recent past activates anterior prefrontal cortex (most often right > left). A schematic of the right hemisphere shows convergence across a large number of PET and fMRI studies that have examined explicit retrieval tasks. Note that the location of this anterior prefrontal region is not homologous to the left and right prefrontal regions associated with memory encoding.

that *the anterior prefrontal cortex, near Brodmann area 10, increases activity when subjects attempt to retrieve information from a specific study episode*. The finding has generalized across a wide range of tasks spanning both recognition and recall, using various kinds of experimental materials, including words, pictures of faces, and objects (Buckner, 1996; figure 57.6). The consistent observation of prefrontal activation and the tendency toward right greater than left lateralization led Tulving and colleagues (1994) to suggest that there is preferential involvement of right prefrontal cortex during conscious attempts to remember the past. This important observation provides a useful heuristic, but it should be noted that the areas tending to show differential activation during retrieval (which localize to anterior prefrontal cortex) often occur concurrently with either bilateral or left-lateralized activations in the posterior prefrontal cortex. Attempting to explicitly retrieve information from a specific study episode additionally recruits the anterior prefrontal cortex at or near Brodmann area 10 (sometimes bilateral but often right > left) (Buckner, 1996; Petrides, Alivisatos, and Evans, 1995).

What role do these anterior prefrontal areas play in retrieval attempt? The answer is not obvious because the behavior of these regions has not been predicted well by many of our preconceived notions of how we go about retrieving information. For example, certain prefrontal areas activated in neuroimaging studies may play a role in the effortful aspects of retrieval attempt (Schacter et al., 1996; Squire, 1992). Situations in which past events come to mind readily have shown less activity within more posterior left prefrontal brain areas compared with situations in which retrieval is more demanding (as measured by reaction times) (Buckner et al., 1998c; Schacter

et al., 1996), suggesting that these prefrontal areas correlate with overall effort. However, activity *within anterior prefrontal regions near Brodmann area 10*, if anything, shows the opposite pattern being most active when retrieval effort is minimal (Buckner et al., 1998c). Thus, the quantitative amount of “effort”—or time on task—does not appear to predict participation of anterior prefrontal cortex in retrieval attempt.

Other ideas, such as the possibility that anterior prefrontal areas participate in the successful retrieval of past information (Rugg et al., 1996), have been suggested and also met with mixed success (Buckner et al., 1998a; Buckner et al., 1998b; Kapur et al., 1995; Nyberg et al., 1995; Wagner et al., 1998a). The collective PET and fMRI data currently suggest that *anterior prefrontal activity increases with the attempt to remember and, under certain circumstances, is unaffected by the history of the stimulus being operated on (whether it is old or new)*. Such a pattern is exactly opposite to that observed for the priming related reductions discussed earlier, which are present independent of the intentions of the subject and correlate with the history of a stimulus.

A final idea, which presently appears to be the forerunner, is that the anterior regions play a role in monitoring the retrieval attempt or evaluating the products of a retrieval attempt. Event-related potential studies have noted that prefrontal scalp signatures of remembering may occur relatively late (see chapter 56), a finding that has a rough correlate in event-related fMRI studies (Buckner et al., 1998b; Schacter et al., 1997). Moreover, working memory studies that place extensive demands on task monitoring sometimes activate these anterior prefrontal regions (MacLeod et al., 1998; Petrides, Alivisatos, and Evans, 1995), suggesting that they likely participate in a fairly generic set of high-level monitoring processes. For incompletely understood reasons, these processes are almost ubiquitously active during the attempt to retrieve information from long-term memory. Moreover, these processes are sensitive to subject-initiated strategies (Wagner et al., 1998a), suggesting that their involvement is dependent on volitional, rather than obligatory, monitoring processes.

It also is worthwhile to consider why we are so dumbfounded by the role of these prefrontal regions in memory processes. We can demonstrate reliably their participation in explicit retrieval processes, suggesting that we have some experimental control over their behavior. However, our many theories and ideas about what it is we are doing when information is retrieved from memory have provided little guidance to hone in on their more specific processing contributions. Current theoretical concepts such as that of retrieval effort and

success cannot account for the available data. This may well be progress. In time we likely will be able to explain why anterior prefrontal areas are activated so consistently during explicit retrieval tasks, which, in turn, will help us to better understand the process of retrieval itself. The functional neuroimaging results to date, which currently are somewhat phenomenological in nature, will drive us to new theoretical ideas about memory in the future. To borrow a quote from Desimone and colleagues (1995), “Neuroscience is sometimes like the game-show ‘Jeopardy’: It provides answers and the trick is to figure out the right questions.” Activation of the anterior prefrontal cortex during explicit retrieval attempts is such an instance.

Conclusions

Human memory encompasses a remarkably complex set of functions that are intertwined intimately with information processing occurring in the here and now. Functional neuroimaging techniques (such as PET and fMRI) provide one source of data helping to elucidate how local changes in net brain activity relate to normal human memory processes. The studies surveyed in this chapter point us toward several conclusions worth reemphasizing. These conclusions represent testable hypotheses about how the brain participates in memory function. They currently are supported by a number of studies in the literature and are able to provide targets for further explorations, helping us to build a cognitive neuroscience of human memory.

1. Posterior dorsal and inferior prefrontal areas are active when subjects engage processing tasks that lead to effective episodic encoding of information, independent of whether these tasks are engaged intentionally by the subject or incidentally.
2. The materials being memorized or the kinds of strategies that the materials being memorized encourage influence laterality of prefrontal areas active during episodic encoding.
3. Strategic frontally mediated processes act interdependently with participation of medial temporal regions to promote memorization of information into a consciously accessible form.
4. Perceptual processing of a stimulus is more efficient after exposure to that stimulus, producing a quicker response (priming) and requiring less net neural activity in a subset of active brain areas.
5. The anterior prefrontal cortex, near Brodmann area 10, increases activity when subjects attempt to consciously retrieve information from a specific study episode.

58 Memory without Remembering and Remembering without Memory: Implicit and False Memories

DANIEL L. SCHACTER AND TIM CURRAN

ABSTRACT Cognitive neuroscience analyses of memory typically rely on experimental paradigms in which participants are asked to remember facts or events presented earlier in the experiment. Here we consider two phenomena of memory that do not involve conscious recollections of previous experiences: implicit memory, the nonconscious influence of a past event on subsequent performance, and false memory, the conscious recollection of an event that never happened. We consider neuropsychological and neuroimaging evidence from four different types of implicit memory phenomena: priming, artificial grammar learning, category learning, and sequence learning. Different brain systems are involved in explicit and implicit memory, and subtypes of implicit memory appear to engage some shared and some distinct mechanisms. We then consider similar kinds of evidence concerning the phenomenon of false recognition—the mistaken conviction that a novel item was encountered previously—that supports a distinction between memory for general similarity or gistlike information on one hand and recollection of specific details on the other. We conclude by considering possible parallels and connections between implicit memory and false memory.

The topics of this chapter—implicit memory and false memory—are relative newcomers to the landscape of memory research. As noted by Schacter (1995a) in the first edition of this volume, the term *implicit memory* had been introduced to the field barely a decade earlier (Graf and Schacter, 1985; Schacter, 1987). Implicit memory occurs when subjects are exposed to target information and are later influenced by that information even when they cannot recollect it consciously. As stated in Schacter (1987, p. 501), “Implicit memory is revealed when previous experiences facilitate performance on a task that does not require conscious or intentional recollection of those experiences.” By contrast, explicit memory “is revealed when performance on a task requires conscious recollection of previous experiences.” Schacter (1995a) summa-

rized the historical development of implicit memory research, considered methodological issues surrounding such research, and reviewed the characteristics of implicit memory that had been revealed by cognitive studies of normal memory and by neuropsychological investigations of amnesic patients. Whereas relatively little was known about the neural correlates of implicit memory when Schacter’s (1995a) chapter was written, a great deal more has been learned during the past few years, mainly from neuroimaging studies and from research with an increasing variety of patient populations. In this chapter we review these recent developments in implicit memory research.

We also consider an even more recent addition to the research agenda of cognitive neuroscience: investigations concerning false memory. The term *false memory* refers to a conscious “recollection” of an event that never happened. False memories are important theoretically because they provide support for the idea that remembering is a fundamentally constructive process, rather than a literal replaying of past events. Cognitive psychologists have known for many years that memory is subject to various kinds of errors, biases, and distortions, dating to the publication of Bartlett’s (1932) pioneering work and even earlier (for historical reviews, see Roediger, 1996; Schacter, 1995b). However, cognitive research on phenomena of constructive remembering, memory distortion, and false memory has been revived recently, stimulated in part by debates and discussions concerning false and recovered memories of childhood trauma (see, for example, Conway, 1997). This rise has been paralleled by a new wave of cognitive neuroscience studies concerning false memories that, during the past few years, has begun to provide insights into the brain processes that underlie constructive memory phenomena (Schacter, Norman, and Koutstaal, 1998). Here we summarize and assess some of the major developments.

Although implicit memory and false memory may appear to be entirely unrelated domains of study, we find it

DANIEL L. SCHACTER Department of Psychology, Harvard University, Cambridge, Mass.

TIM CURRAN Department of Psychology, Case Western Reserve University, Cleveland, Ohio

interesting to consider them together, for two reasons. First, whereas traditional studies of memory are linked by a common feature—subjects recall or recognize what has been presented to them previously in an experiment—neither implicit memory nor false memory involves remembering events that occurred previously. We find it intriguing to consider what we have learned about accurate recollections of past experiences by studying memory without remembering and remembering events that never happened. Second, we believe that there are some points of theoretical contact between studies of implicit memory and false memory, which we touch on briefly in our concluding section.

Implicit memory

Although observations concerning what we now call implicit memory have a long history (see Schacter, 1987), during the 1960s and 1970s—and especially during the early 1980s—systematic experimental evidence began to accumulate indicating that effects of prior experiences could be expressed without, and dissociated from, intentional or conscious recollection. The terms *implicit* and *explicit memory* were put forward in an attempt to capture and describe essential features of the observed dissociations (for a related distinction between declarative and nondeclarative memory, see Squire, 1994).

The term “implicit memory” subsumes various different types of phenomena, and we do not attempt to comprehensively review all of them here (for review and discussion, see Roediger and McDermott, 1993; Salmon and Butters, 1995; Schacter and Buckner, 1998b; Stadler, 1997; Wiggs and Martin, 1998). Instead we focus on recent studies concerned with four different phenomena of implicit memory: priming, artificial grammar learning, category learning, and sequence learning.

PRIMING Priming refers to a change in the ability to identify or produce an item as a result of a particular prior encounter with the item (Schacter and Buckner, 1998b; Tulving and Schacter, 1990). Priming is assessed with tests in which subjects attempt to identify briefly flashed stimuli—complete words, stems, or fragments—with the first word that comes to mind, or produce items from a category in response to a category cue. Data concerning the cognitive and behavioral properties of priming effects on these and related tests have been summarized in several comprehensive reviews (Roediger and McDermott, 1993; Schacter, Chiu, and Ochsner, 1993; Tenpenny, 1995).

Insights into the brain systems involved in priming were provided initially by studies of amnesic patients. Beginning with the pioneering studies of Warrington

and Weiskrantz (1974), a variety of studies have shown that amnesic patients with damage to medial temporal and diencephalic brain regions, as well as severe deficits in explicit memory, nonetheless often show normal priming effects. Intact priming in amnesia has been shown for both visual information (Graf, Squire, and Mandler, 1984) and auditory information (Schacter, Church, and Treadwell, 1994), for nonsense words (Keane et al., 1995) and novel objects (Schacter, Cooper, and Treadwell, 1993), for various types of conceptual information (Carlesimo, 1994), and under conditions in which explicit memory does not exceed chance levels (Hamann and Squire, 1997).

Amnesic patients do not, however, always show normal priming effects. When priming is based on general information about a familiar word or object, amnesics typically show intact priming (for discussion of this point, see Ostergaard and Jernigan, 1993; Hamann, Squire, and Schacter, 1995). But several studies have shown that amnesics sometimes exhibit impaired priming when the priming effects depend on highly specific information about the pairing of unrelated words (Schacter and Graf, 1986; Shimamura and Squire, 1989) or the exact perceptual details of previously presented words (Kinoshita and Wayland, 1993; Schacter, Church, and Bolton, 1995). Nonetheless, conditions exist in which amnesics can show priming for specific pairing of unrelated items (Gabrieli et al., 1997) and perceptual details of recently studied words (Vaidya et al., in press). Although the relation between priming based on general versus specific features of a word or object is not well understood (for data and discussion, see Curran, Schacter, and Bessenhoff, 1996; Tenpenny, 1995), studies by Marsolek and colleagues have delineated a number of experimental conditions in which priming based on general information is mediated primarily by the left hemisphere whereas priming based on specific information appears to be based primarily on the right hemisphere (e.g., Marsolek, Kosslyn, and Squire, 1992; Marsolek, Schacter, and Nicholas, 1996).

Recent studies using neuroimaging techniques have provided additional insights into brain regions that are associated with priming effects. Several studies using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have shown that perceptually based visual priming is accompanied by reduced activity in posterior extrastriate regions that have previously been implicated in visual word and object processing (Buckner et al., 1998; Schacter, Alpert, et al., 1996; Squire et al., 1992; for review, see Schacter and Buckner, 1998a; Wiggs and Martin, 1998). These studies complement findings reported by Gabrieli and colleagues (1995) that perceptual priming is absent in a patient with damage

to right extrastriate cortex. Thus the imaging and neuropsychological data converge on the conclusion that posterior cortical regions play an important role in perceptually based priming effects.

Neuroimaging studies also indicate that conceptually based priming effects are accompanied by reduced activity in prefrontal cortex (Buckner et al., 1998; Demb et al., 1995). As Schacter and Buckner (1998a) point out, it is too simplistic to equate perceptual priming with reduced activity in posterior areas and conceptual priming with reduced activity in more anterior reductions. Nonetheless, the consistent finding of priming-related reductions in various cortical areas that are typically not damaged in amnesic patients fits well with the more general conclusion that such areas make an important contribution to various kinds of priming effects (for an electrophysiological index of implicit memory that may be related to priming, see Rugg et al., 1998).

A persisting issue in neuroimaging studies of priming concerns whether priming-related changes in blood flow are produced by nonconscious, implicit expressions of memory or whether they are related to "contamination" from voluntary or involuntary explicit memory (for extensive discussion of this issue, see Schacter and Buckner, 1998a). For instance, in an early study of priming on a word stem completion test by Squire and colleagues (1992), priming-related extrastriate blood flow reductions were accompanied by a priming-related increase in right parahippocampal gyrus. Because levels of explicit memory were quite high under the particular conditions used in this experiment, Squire and colleagues (1992) and Schacter, Alpert, and colleagues (1996) noted that the right parahippocampal activation might reflect voluntary or involuntary explicit memory for previously studied words. Schacter, Alpert, and colleagues (1996) tested this idea by using an encoding task that produced low levels of explicit memory. They found a priming-related extrastriate blood flow reduction together with no evidence of parahippocampal activation, thus supporting the idea that the parahippocampal activation observed by Squire and colleagues (1992) reflected contamination from explicit memory.

More recently, Beaugrand and colleagues (1998) reported evidence of hippocampal activation during priming of a semantic-category decision task, following a subliminal encoding task that produced little or no evidence of explicit memory. Although intriguing, interpretation of this finding is difficult because of the presence of several key confoundings in the study. Evidence for hippocampal activation emerged from comparison of a primed semantic category decision condition and a nonprimed semantic-category decision task. Unfortunately, the two conditions differed in many ways: In the primed

condition subjects decided whether previously studied words belonged to the category of "animals," and in the unprimed condition they decided whether an entirely different set of words belonged to the category of "tools"; the order of primed and unprimed scans was not counterbalanced; and because of the different item sets used in the primed and unprimed scans, there were more "yes" responses required in the primed than the unprimed scans. In view of these serious methodological problems, further studies will be needed to evaluate the possibility that hippocampal activation is linked to implicit memory.

ARTIFICIAL GRAMMAR LEARNING Reber (1967) developed an artificial-grammar-learning task in which subjects are exposed to seemingly random consonant strings that, unbeknownst to them, were generated from a complex set of rules (an "artificial grammar"). After viewing a list of grammatical stimuli, subjects are able to discriminate between grammatical and nongrammatical strings despite their limited ability to articulate the information upon which their judgments are based. Reber (1967) first coined the term "implicit learning" to describe this ability to learn complex information in the absence of awareness (reviewed by Reber, 1989). In contrast to implicit memory, which primarily emphasizes limited awareness and/or intention during retrieval, implicit learning primarily emphasizes limited awareness/intention during encoding (Buchner and Wippich, 1997; Stadler and Roediger, 1997).

Reber (1967, 1989) originally maintained that subjects in an artificial-grammar-learning experiment develop an abstract representation of the rules that comprise the grammar. In contrast, episodic accounts maintain that subjects learn by storing individual exemplars (Vokey and Brooks, 1992; Whittlesea and Dorken, 1993). Episodic theories can account for subjects' ability to classify grammatical, but nonstudied, strings correctly by positing that judgments are based on the global similarity between the test item and stored exemplars (e.g., Hintzman, 1986). Grammatical test items will tend to be more similar to encoded exemplars than nongrammatical items, so subjects will be more likely to classify grammatical items accordingly.

The debate over abstractionist and episodic theories will not be settled here (see Dienes and Berry, 1997; Neal and Hesketh, 1997; and accompanying commentaries), but one possible resolution is that implicit learning leads to abstract representation whereas explicit learning results in exemplar storage. Amnesic patients can learn to make grammaticality judgments as accurately as control subjects, despite their recognition impairment for studied exemplars (Knowlton, Ramus, and

Squire, 1992; Knowlton and Squire, 1994, 1996). Knowlton, Ramus, and Squire (1992) originally concluded that normal grammaticality judgments indicated spared implicit abstraction and that poor recognition performance indicated impaired exemplar memory. More recently, Knowlton and Squire (1996) have argued for both abstract and exemplar-specific implicit learning. Exemplar-specific implicit learning was inferred from amnesic patients' normal sensitivity to the frequency of letter bigrams and trigrams (chunks) that were in the original training set. Abstract implicit learning was inferred from amnesic patients' normal ability to transfer learning across physical changes in the letters entered into the grammar (though letter-set transfer is not universally agreed to demand an abstract representation; Neal and Hesketh, 1997; Whittlesea and Dorken, 1993). Reber has recently concurred that implicit learning can result in both abstract and episodic representations (Reber, Allen, and Reber, *in press*).

Currently, there is no evidence to link grammar learning directly to particular neural mechanisms beyond the data from amnesic patients indicating that medial temporal regions are not necessary for such learning to occur. Unlike other implicit learning tasks (described in the following subsections), patients with Huntington's disease (HD, Knowlton et al., 1996) and Parkinson's disease (PD, Reber and Squire, *in press*) show normal artificial grammar learning, so the striatum (which is typically damaged in such patients) does not appear to make a critical contribution.

CATEGORY LEARNING Other evidence for priming-like effects has been documented in a task that is conceptually similar to artificial grammar learning. Artificial grammar learning can be considered to be a special case of category learning in that subjects are required to judge whether individual stimuli (e.g., consonant strings) are members of a larger class (e.g., a grammar). Parkinson's disease patients (Reber and Squire, *in press*) as well as patients with amnesia (Knowlton and Squire, 1995; Knowlton, Squire, and Gluck, 1994) show normal category learning in a task that requires subjects to decide if novel dot patterns belong to the same category as a set of training patterns (following Posner and Keele, 1968). A recent fMRI experiment suggests that processing of categorical dot patterns elicits less posterior, occipital activation than does processing of noncategorical patterns (Reber, Stark, and Squire, 1998). Thus perceptual categorization may involve mechanisms similar to those that support perceptual priming.

Another form of implicit category learning has been demonstrated with probabilistic categorization tasks. These classification tasks require subjects to predict

which of two outcomes (e.g., sunshine or rain) will follow particular cue combinations (e.g., combinations of 1 to 4 geometric symbols). The cues are probabilistically predictive of outcomes, so that subjects' predictive accuracy increases with training. As observed for learning artificial grammars and novel dot patterns, amnesic patients show normal classification learning (Knowlton, Gluck, and Squire, 1994; Knowlton, Mangels, and Squire, 1996; Reber, Knowlton, and Squire, 1996). Unlike these other forms of categorical learning, probabilistic classification learning is impaired in patients with PD (Knowlton, Mangels, and Squire, 1996) and HD (Knowlton et al., 1996).

Impaired performance in HD and PD patients is most often attributed to striatal neuropathology. Willingham (*in press*) has suggested that the striatum (along with the supplementary motor area) enables the learning of repeated response sequences, but such information does not appear to be learned in the probabilistic classification task. However, primary and secondary effects of PD and HD can be more widespread, with frontal impairments especially prevalent (Jacobs, Stern, and Mayeux, 1996), so any cognitive/behavioral deficits found in these disorders can only be tentatively linked to striatal dysfunction. Understanding why PD and HD patients perform more proficiently on some categorical learning tasks than others, as well as understanding the precise neuropathology responsible for their classification deficit, remains an important goal for future research.

SEQUENCE LEARNING Implicit sequence learning is another task that, like probabilistic classification learning, requires subjects to learn associations between multiple cues and outcomes, and it has been more clearly linked to the striatum. Implicit sequence learning has been primarily studied with the serial reaction time (SRT) task (Nissen and Bullemer, 1987). Subjects typically view a stimulus moving across different visual locations and press location-corresponding response keys as quickly as possible. Normal subjects (e.g., Curran and Keele, 1993; Reed and Johnson, 1994; Stadler, 1995; Willingham, Nissen, and Bullemer, 1989) and patients with amnesia (e.g., Curran, 1997a; Nissen and Bullemer, 1987; Reber and Squire, 1994) show improved performance when stimulus locations follow a repeating pattern, compared to conditions in which stimulus locations are randomly determined. This form of learning does not depend on explicit knowledge (for contrary views, see Perruchet and Amorim, 1992; Shanks and St. John, 1994). SRT learning is impaired in both patients with PD (e.g., Jackson et al., 1995) and patients with HD (e.g., Willingham and Koroshetz, 1993).

Impaired sequence learning in PD and HD patients suggests a striatal contribution that has been confirmed by SRT studies using PET (Berns, Cohen, and Mintun, 1997; Grafton, Hazeltine, and Ivry, 1995; Hazeltine, Grafton, and Ivry, 1997; Rauch et al., 1995) and fMRI (Rauch et al., 1998, 1997). These studies additionally have identified learning-related changes in primary motor cortex, supplementary motor areas, premotor cortex, thalamus, parietal cortex, and occipital cortex (for reviews, see Curran, 1997b; Keele et al., 1998). The distribution of learning-related activity suggests that SRT learning involves changes in perceptual and motor areas that subserve visually guided movement. This observation is conceptually similar to our previous conclusion that visual priming is accompanied by reduced activity in posterior extrastriate regions implicated in visual word and object processing. Generally, implicit learning and memory appear to involve changes in information processing systems that normally contribute to task performance. However, whereas priming typically leads to decreased activity in implicated areas, sequence learning most often leads to increases in activity. Ungerleider (1995) has previously noted this apparent contradiction, and has suggested that early stages of perceptual-motor learning may involve activity decreases followed by increases in later stages. Across the temporal course of SRT learning, thalamic activity initially decreases, then later increases (Rauch et al., 1998). Rauch and colleagues hypothesize that these effects reflect input from distinct striatal circuits that, respectively, suppress and enhance thalamic activity. Further understanding of the functional significance of learning-related increases and decreases in activity will depend on more detailed temporal information as well as better understanding of the neurophysiology of implicated areas.

The precise functional anatomy of sequence learning depends on the nature of the information that is learned. For example, under otherwise identical conditions, PET experiments have shown that learning-related brain areas differ between visuospatial sequences (Grafton, Hazeltine, and Ivry, 1995) and color sequences (Hazeltine, Grafton, and Ivry, 1997). Based on these PET results as well as behavioral experiments indicating both independent (Mayr, 1996) and interdependent (Schmidtke and Heuer, 1997) learning effects when stimulus/response characteristics of sequences are varied, Keele and colleagues (1998) suggested the existence of two distinct sequence learning systems (cf. Curran and Keele, 1993). An implicit dorsal system learns response-based sequences within a given stimulus modality (e.g., visuospatial, color, auditory). A ventral system can learn cross-dimensional sequences (e.g., sequences composed of a combination of visual and auditory signals; Schmidtke and Heuer, 1997)

in either an implicit or explicit manner. Keele and colleagues also hypothesize that the ventral cross-dimensional system may be better able to learn complex, higher-order associations between multiple stimuli (cf. Curran, 1997a) than the dorsal unidimensional system. Both systems are hypothesized to depend on a striatal switching function (Hayes et al., 1998) that controls access to learned sequence chunks (cf. Stadler, 1995).

False memory

We now turn our attention from nonconscious influences of past experiences to those situations in which people consciously recollect experiences that never occurred.

When we use such phrases as “false memory,” “illusory memory,” or “remembering events that never happened,” what exactly do we mean? At one extreme, consider the case of a patient who reports a detailed recollection of having served as an officer in Vietnam and describes vividly war episodes in which he acted heroically to save lives—even though government records show that the patient never went to Vietnam. The patient has produced a confabulation, and there can be little doubt that his subjectively compelling recollective experience deserved to be called a false or illusory memory. At another extreme, however, consider a participant in a recognition memory experiment who has studied a list of words and makes old/new judgments about previously studied words and novel words that are unrelated to studied items. Most participants will say “old” to at least a few new words—that is, they will commit a few false alarms. The participant is claiming memory for an event that never happened (i.e., seeing a word in a list even though it was never presented) and so in some sense is exhibiting a false or illusory memory. However, most researchers would probably be reluctant to apply these labels here, because false alarms to unrelated words are relatively infrequent, tend not to be accompanied by strong subjective convictions that the information was previously encountered, and are often viewed as providing estimates of guessing biases.

In most research settings, the phenomena that have been cited as evidence of “false memories” generally fall somewhere between the two extremes of detailed confabulation on the one hand and the more innocuous false alarm to a novel word on the other. Here we focus on the phenomenon of *false recognition*, which occurs when subjects are shown novel items (e.g., words or pictures) and incorrectly claim to have encountered them earlier in the experiment (for review and discussion of confabulation and related kinds of false recall, see Moscovitch, 1995; Schacter, Norman, and Koutstaal, 1998).

False recognition is typically inferred from “old” responses to novel items that are in some way related (conceptually or perceptually) to previously studied items—that is, false alarms above and beyond the “baseline” level of false alarms to unrelated novel items noted in the preceding paragraph, (cf. Roediger and McDermott, 1995; Underwood, 1965).

False recognition has been studied experimentally since the classic work of Underwood (1965), which used a continuous recognition paradigm in which subjects make old/new decisions about previously studied words, new words preceded by an associated word (related lures), and new words that are not preceded by an associated word (unrelated lures). False recognition in this paradigm takes the form of a small increase in false alarms to related lures compared to unrelated lures. More recent research has shown that stronger false recognition effects can be obtained when participants study large numbers of items that are conceptually or perceptually similar to a novel test item (e.g., Shiffrin, Huber, and Marinelli, 1995).

Roediger and McDermott (1995) provided an especially striking demonstration of robust false recognition. They modified and extended a procedure developed initially by Deese (1959) in which subjects hear lists of associated words (e.g., *candy*, *sour*, *sugar*, *bitter*, *good*, *taste*, *tooth*, etc.) that all converge on a nonpresented “theme word” or false target (e.g., *sweet*). Roediger and McDermott reported exceptionally high levels of false recognition (e.g., 80%) to the theme words. The level of false recognition responses was indistinguishable from the hit rate to studied items, and false recognitions were accompanied by high confidence and a sense of detailed recollection. Subsequent studies have delineated various characteristics of this powerful false recognition effect (e.g., Mather, Henkel, and Johnson, 1997; McDermott, 1997; Norman and Schacter, 1997; Payne et al., 1996; Robinson and Roediger, 1997).

FALSE RECOGNITION AND AMNESIC PATIENTS Neuropsychological evidence concerning the basis of robust false recognition has been provided by several recent studies of amnesic patients. Using the Deese/Roediger-McDermott procedure, Schacter, Verfaellie, and Pradere (1996) found that, not surprisingly, amnesic patients with damage to either the medial temporal region (i.e., anoxia, encephalitis) or the diencephalic regions (i.e., Korsakoff patients) showed significantly reduced levels of true recognition compared to matched controls: Amnesics made fewer hits to studied items and more false alarms to unrelated lure words than did control subjects. But despite making more false alarms to unrelated lures, amnesic patients made significantly fewer false alarms to semantically related lure words; that is, they

showed a smaller false recognition effect than did controls.

These findings have recently been extended to the domain of perceptual false recognition: After studying lists of perceptually related words (e.g., *lake*, *fake*, *sake*), amnesic patients committed fewer false recognition errors to perceptually related lure words (e.g., *rake*) than did controls (Schacter, Verfaellie, and Anes, 1997). Similarly, Koutstaal and colleagues (in press) examined false recognition of abstract visual patterns in amnesic patients, using a prototype recognition procedure that is similar in some respects to the paradigms used in category learning experiments described earlier. Koutstaal and colleagues found robust false recognition to prototypes in control subjects, together with significantly reduced false recognition of prototypes in amnesic patients.

The overall pattern of results from the foregoing studies indicates that the medial temporal/diencephalic regions that are damaged in amnesic patients, which have long been linked to veridical recognition, are also involved in false recognition. Specifically, it has been proposed (Schacter, Verfaellie, and Pradere, 1996; Schacter, Norman, and Koutstaal, 1998) that medial temporal areas are involved in the encoding and/or retrieval of semantic and perceptual-gist information (Brainerd, Reyna, and Kneer, 1995) or global-similarity information (Hintzman and Curran, 1994) that supports robust false recognition. Amnesia typically reduces false recognition by impairing this proposed mechanism, but the false recognition rate of amnesic patients can exceed that of control subjects when experimental conditions are created that increase control subjects’ episodic memory for actually studied words, thus allowing them—but not amnesic patients—to suppress their false recognition responses (Schacter, Verfaellie, and colleagues, 1998; cf. Brainerd, Reyna, and Kneer, 1995).

A related line of studies has examined false recognition in amnesic patients using a procedure, introduced by Underwood and Zimmerman (1973) and developed further by Reinitz and his colleagues (e.g., Reinitz and Demb, 1994), that produces “memory conjunction errors.” In this paradigm, conjunction false alarms occur when subjects incorrectly claim to have studied lure words (e.g., *handgun*) that are formed by recombining features of studied compound words (e.g., *handstand*, *shotgun*); similar effects have been observed when features of faces or of nonsense syllables are recombined after study. Reinitz, Verfaellie, and Milberg (1996) found that control subjects made more “old” responses to previously studied compound words than to conjunction lures. Amnesic patients, by contrast, made similar numbers of “old” responses to the two types of items: Amnesics made fewer “old” responses to studied words than

did controls, and made comparable numbers of false alarms to conjunction lures.

Kroll and colleagues (1996) used similar procedures in experiments that included patients with left or right hippocampal damage, reporting that patients with left but not right hippocampal damage showed elevated rates of memory conjunction errors to recombined words, whereas both patient groups showed higher levels of conjunction errors than did controls with recombined faces. Kroll and colleagues (1996) suggested that hippocampal lesions interfere with binding features of an episode into a cohesive representation.

FALSE RECOGNITION IN NONAMNESIC PATIENTS Several recent case studies have shown dramatic increases of false recognition in patients with lesions to various aspects of the frontal lobes. For instance, Parkin and colleagues (1996) reported elevated false recognition in a patient who had suffered a ruptured anterior communicating artery aneurysm that produced left frontal lobe atrophy. False recognition of nonpresented materials was accompanied by high confidence, but was nearly eliminated when lure items were perceptually dissimilar to studied items.

In a case study similar to the foregoing reports, we found extremely high levels of false recognition to words, nonsense syllables, pictures, and sounds in a patient (B. G.) who had suffered an infarction to the right frontal lobe (Curran et al., 1997; Schacter, Curran, et al., 1996). As with Parkin and colleagues' patient J. B., however, false recognition in patient B. G. was reduced when lure items did not share the general features of studied items. Thus, for example, after studying pictures of animate objects from various categories, B. G. made frequent false alarms to novel pictures from studied categories, but virtually never made false alarms to pictures of animals (Schacter, Curran, et al., 1996). Subsequent experiments showed that false recognition in patient B. G. could also be reduced by requiring him to make encoding judgments that resulted in detailed recollections of studied items (Curran et al., 1997). The overall pattern of results suggests that when making recognition judgments, patient B. G. (like patient J. B.) relies excessively on general similarities between study and test items unless he is provided with an encoding task that promotes the accessibility of item-specific information.

Studies of split-brain patients also highlight the distinction between general similarity and item-specific information. A series of experiments has shown that the left hemisphere is often prone to false recognition based on conceptual or perceptual similarity between lure items and previously studied information—words, faces, visual

patterns, or scenes—whereas the right hemisphere tends to respond “old” only when study and test items are identical (Metcalf, Funnell, and Gazzaniga, 1995). Finally, several recent studies have shown that older adults are often more prone to false recognition based on general similarity or gist information than are younger adults (for review, see Schacter, Koutstaal, and Norman, 1997).

NEUROIMAGING OF FALSE RECOGNITION Only a handful of studies have examined false recognition with neuroimaging techniques, mainly using the Deese/Roediger-McDermott semantic associates paradigm. The general conclusion from studies using PET (Schacter, Reiman, et al., 1996), fMRI (Schacter, Buckner, et al., 1997), and ERPS (Duzel et al., 1997; Johnson et al., 1997) is that the same or similar patterns of brain activity are observed during true and false recognition, with some small differences occurring under particular experimental conditions. More specifically, differences between true and false recognition have been reported when true and false targets are tested in separate “blocks,” with PET data indicating greater activation in the left superior temporal gyrus during true than false recognition and trends for more anterior prefrontal regions during false than true recognition (Schacter, Reiman, et al., 1996), fMRI data indicating greater right anterior frontal activity during false than true recognition (Schacter, Buckner, et al., 1997), and ERP data indicating differences between true and false recognition in frontal and left temporoparietal electrode sites (Johnson et al., 1997). However, when true and false targets are randomly intermixed during recognition testing, as can be done with ERPs and “event-related” fMRI, no significant differences in brain activity underlying true and false recognition have been reported (Duzel et al., 1997; Johnson et al., 1997; Schacter, Buckner, et al., 1997).

One other notable finding to emerge from neuroimaging studies concerns the time course of brain activation. Using event-related fMRI, Schacter, Buckner, and colleagues (1997) reported that anterior prefrontal regions showed a delayed onset of activity in comparison to all other regions that were activated during true and false recognition. Schacter, Buckner, and colleagues (1997) suggested that anterior prefrontal areas might be involved in postretrieval monitoring activities, which in turn may be related to criterion-setting processes that play an important role in false recognition (see Johnson et al., 1997; Schacter, Norman, and Koutstaal, 1998).

Conclusions

The research we have considered in this chapter indicates that neuropsychological evidence from various

patient populations and neuroimaging studies of healthy volunteers are beginning to illuminate the neural underpinnings of the two phenomena we have characterized as “paradoxical”: implicit memory and false memory. Having considered the two separately, we now conclude by asking about possible connections between them.

One theme that occupies a prominent place in both literatures concerns the contrast between memory for general or gist information on one hand versus memory for specific exemplars or items on the other. In studies of priming, for example, it has been suggested that priming of generic or abstract representations may depend on different mechanisms than does priming specific perceptual features (cf., Curran, Schacter, and Bessenhoff, 1996; Marsolek, Kosslyn, and Squire, 1992; Marsolek, Schacter, and Nicholas, 1996). Studies of artificial grammar learning and category learning have also been concerned with the distinction between abstract and exemplar-based learning (e.g., Knowlton and Squire, 1996; Reber, Allen, and Reber, in press). In studies of false memories, the idea that false recall and recognition reflect the influences of gist or general similarity information, whereas veridical recall and recognition reflect the influence of item-specific information, has assumed central stage (e.g., Brainerd, Reyna, and Kneer, 1995; Curran et al., 1997; Payne et al., 1996; Schacter, Norman, and Koutstaal, 1998). To what extent is the gist or general similarity information that drives false memories the same as or similar to the generic or abstract information that underlies certain kinds of implicit memory effects? Earlier we reviewed data indicating that amnesic patients typically show normal priming effects after studying familiar words. Yet we also considered evidence that amnesic patients exhibit decreased gist-based false recognition after studying lists of semantically related words (Schacter, Verfaellie, and Pradere, 1996) or perceptually related words (Schacter, Verfaellie, and Anes, 1997). These kinds of findings suggest that priming and false recognition are based, at least in part, on different underlying mechanisms. Likewise, we noted recent evidence indicating that amnesic patients show reduced false recognition of visual prototypes (Koutstaal et al., in press), even though other studies have documented normal implicit prototype learning in amnesics (Knowlton and Squire, 1993). These findings, too, suggest possible differences between the mechanisms that support false recognition and implicit learning of prototypes.

To link the two domains of research more tightly, it will be necessary to carry out studies in which implicit and explicit measures of true and false memories are examined within a single experiment. Some evidence of this kind already exists. As noted earlier, in their study

of memory conjunction errors Reinitz, Verfaellie, and Milberg found that control subjects made more “old” responses to previously studied words than to conjunction lures, whereas amnesic patients made similar numbers of “old” responses to the two types of items. In addition to this explicit recognition test, however, Reinitz, Verfaellie, and Milberg (1996) also examined priming of studied compound words and recombined items using a perceptual identification test, where subjects tried to identify briefly flashed stimuli. On this implicit measure, both amnesic patients and controls showed more priming for studied than recombined words, and there were no between-group differences in the magnitude of priming. Thus, even though amnesics showed no discrimination between studied items (true memories) and conjunction lures (false memories) on an explicit measure, they did show significant (and normal) levels of discrimination between the two on an implicit measure.

McDermott (1997) has also reported relevant data. In her experiments, subjects initially studied the Deese/Roediger-McDermott semantic associate lists, and were then given a stem completion test in which they provided the first word that came to mind in response to stems that could be completed with studied words, related lures, or unrelated items. She found that subjects showed significant “false priming” for the nonpresented semantic associates: When given a stem that could be completed with a nonpresented semantic associate, subjects provided the related false target at greater than baseline levels (e.g., after studying *candy*, *sour*, *sugar*, *bitter*, and related associates, when given the word stem “swe___,” subjects were primed to respond with *sweet*). Would such effects also be observed to the same extent in amnesic patients who, as reported by Schacter, Verfaellie, and Pradere (1996), show reduced false recognition of semantic associates on explicit measures? Experiments that address such questions should help to clarify the relations between the intriguing phenomena of implicit memory and false memory that have, perhaps paradoxically, enriched our understanding of what it means to remember experiences that really did happen.

ACKNOWLEDGMENTS The writing of this chapter was supported by National Institute on Aging grant AG08441 and a grant from the Human Frontiers Science Program.

Introduction

WILLEM J. M. LEVELT

Language evolved as the species-specific communication system of *homo sapiens*. Although its evolutionary history will always remain intractable, it is reasonable to suppose that a major selective pressure derived from the need to maintain coherence in ever-growing cooperative clans. Our closest relatives in nature, the old world primates, achieve this bonding largely by grooming and, as Dunbar (1996) has shown, the amount of time spent on grooming indeed increases rapidly with group size across primate species. Bonding-by-grooming, however, becomes impractical for the much larger clan size that is typical of a human hunter-gatherer society. Clearly, language can serve this function of social bonding and much more. It is particularly well designed for communication in a society of individuals that have a “theory of mind” (Premack and Woodruff, 1978). When interactants mutually interpret their behaviors as proceeding from beliefs, wishes, hopes, and the like, as is the case in human societies only (Tomasello and Call, 1997), it is certainly useful to have a communicative system that can express such recursive attributions as “A believes that B knows X.” But it is a vain hope to *predict* the design of natural languages from the evolutionary pressures that must have shaped it. More is known about which areas of the primate brain were engaged to serve these new communicative functions. This is, first of all, the old call system, which is one of phonation. It involves the caudal midbrain structures and is expressive of the animal’s emotions (Müller-Preuss and Ploog, 1983). Neocortical control is restricted to input from the (limbic) anterior cingulate gyrus. This evolutionary old system is still involved in the modulation of vocal fold activity during speech, in particular intonation, which remains highly expressive of emotion. However, in our species phonation is clearly under

neocortical control: We can sing and we can feign emotion in speech. The same is true for the new supralaryngeal system. It modulates phonation in the time-frequency domain, i.e., it controls articulation. MacNeilage (1998) outlines the evolutionary precursors of this syllabic, articulatory system. Its evolution corresponds to further specialization of the face area in the primary motor cortex and to a vast expansion of supplementary and premotor cortices. At the same time, left temporal lobe areas adjacent to the primary auditory cortex became more specialized for the storage of phonological codes. Various left-hemisphere perisylvian areas (temporal, parietal, insular, frontal) became involved with the complexities of linguistic processing, ranging from semantic to syntactic, morphological, phonological, and phonetic analysis and synthesis. But evolution did not prepare us for reading. It is, in fact, an unexplained accident that most of us can learn to read. The skill is obviously parasitical on the reader's pre-existing linguistic and visual competence, but the specifics of grapheme-to-phoneme mapping (in alphabetic systems) requires the engagement of cortical structures that did not evolve for that purpose and that may vary from learner to learner. Given this biologically secondary status of reading, it is at least remarkable that the large majority of language-related brain-imaging studies involve printed, not spoken language as input.

The aim of this Language section is to review major relations between the functional and the neural architecture of language. The functional architecture of language use, i.e., its organization as a behavioral system, is the domain of psycholinguistics. Traditionally, the field is partitioned as the study of language production (speaking, signing), language comprehension, the development of these skills (language acquisition), and the study of their disorders. This schema is also followed in the present section. In their chapter on language production, Indefrey and Levelt relate the functional architecture of the process of speaking, in particular the generation of spoken words, to a wide range of recent imaging results. Language comprehension, always the more active field of research, is covered by two chapters. The first one, by Norris and Wise, deals with accessing words from auditory or visual input and relates the functional organization of word recognition to the neural architecture involved. The second one, by Brown, Hagoort, and Kutas, reviews the neurophysiology and hemodynamics of postlexical processing, i.e., the integration of words in their larger syntactic and se-

mantic context during sentence processing. Two further chapters are dedicated to the acquisition of linguistic skills. Mehler and Christophe discuss the initial stage, the infant's discovery of the sound structure of the single or multiple languages with which it is confronted. Stromswold reviews the further maturation of linguistic skills, both normal and disordered, from the perspective of the human brain's predisposition for language. Both chapters consider in some detail the neural architecture that supports this rapid buildup of linguistic competence. The final pair of chapters is dedicated to language disorders. Saffran, Dell, and Schwartz review recent computational accounts of the major aphasic disorders: Can aphasic syndromes be modeled by "damaging" the normal computational architecture? In their chapter, Dronkers, Redfern, and Knight discuss language disorders from the perspective of the damaged cortical structures involved. Their "triangulation" approach requires a detailed analysis of functional components combined with a substantial database of brain and behavioral patient data.

Together, these seven chapters provide optimal coverage of the cognitive neuroscience of language. But the coverage is, by no means, intended to be comprehensive. Not only is the literature, including such a classical source as Caplan's (1992) book, already vast, but the recent volcanic eruption of imaging studies of language use is transforming the field in ways that will become fully apparent only after the first dust has settled. Meanwhile, the best coverage of the field can be found in Stemmer and Whitacker (1998) and Brown and Hagoort (1999).

59 The Neural Correlates of Language Production

PETER INDEFREY AND WILLEM J. M. LEVELT

ABSTRACT This chapter reviews the findings of 58 word production experiments using different tasks and neuroimaging techniques. The reported cerebral activation sites are coded in a common anatomic reference system. Based on a functional model of language production, the different word production tasks are analyzed in terms of their processing components. This approach allows a distinction between the core process of word production and preceding task-specific processes (lead-in processes) such as visual or auditory stimulus recognition. The core process of word production is subserved by a left-lateralized perisylvian/thalamic language production network. Within this network there seems to be functional specialization for the processing stages of word production. In addition, this chapter includes a discussion of the available evidence on syntactic production, self-monitoring, and the time course of word production.

In reading the neuroscience literature on language production, one might infer that producing language simply means producing words. Neuroimaging studies of language production typically require subjects to generate (silently) words in response to other words (as in verb generation)—words of a particular semantic category, names of depicted objects, words beginning with a particular phoneme (or letter), and the like. Such studies have provided a wealth of information on the neurophysiology of lexical access, but they should not obscure our perspective on the larger speech production process. Speaking is, after all, our most complex cognitive-motor skill, designed by evolution to support communication in large clans of *homo sapiens*. A vast network of brain structures, both cortical and subcortical, contributes to the high-speed generation of utterances in never-identical communicative settings. It also generates the ever-babbling internal speech, speech whose representational functions are still fallow research territory.

In this chapter, therefore, we begin with a summary outline of the functional organization of speaking, laying out the processing components involved, including grammatical encoding, phonological encoding, and self-monitoring. These components then offer a structure for

the subsequent review of neuroimaging studies, most of them word production studies.

The functional organization of language production

The interactive generation of utterances in conversation, the evolutionary basic setting for language use, involves a multicomponent processing system. It can map communicative intentions onto articulatory gestures, which in turn produce the auditory signals from which the interlocutor can derive or recognize these intentions. Figure 59.1 diagrams the major processing components involved (roughly as defined in Levelt, 1989). Although the modeling of component processes and their interaction still differs substantially among theories of language production (see, in particular, the BBS commentaries to Levelt, Roelofs, and Meyer, 1999), there is reasonable consensus about the major components involved in the generation of speech.

It makes both functional and neuropsychological sense to partition these components as follows. There is, on the one hand, a rhetorical/semantic/syntactic system. It decides on the communicatively effective information to express, puts it in terms of linguistically expressible conceptual structures (“messages”), whereupon these messages trigger the generation of ordered lexicosyntactic structures (“surface structures”). On the other hand, there is also a phonological/phonetic system whose aim it is to generate the appropriate articulatory shape for these surface structures. Both systems have access to a huge mental lexicon. The rhetorical/semantic/syntactic system has, in addition, access to communicatively relevant perceptual and memory systems which represent the speaker’s external and internal world. The form-generating system has access to a mental syllabary. Let us now turn to the processing components in slightly more detail.

CONCEPTUAL PREPARATION In preparing a message for expression, we exercise our social and rhetorical competence. An effective utterance will mind the knowledge state of the listener, the intention to be realized, the

PETER INDEFREY and WILLEM J. M. LEVELT Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands

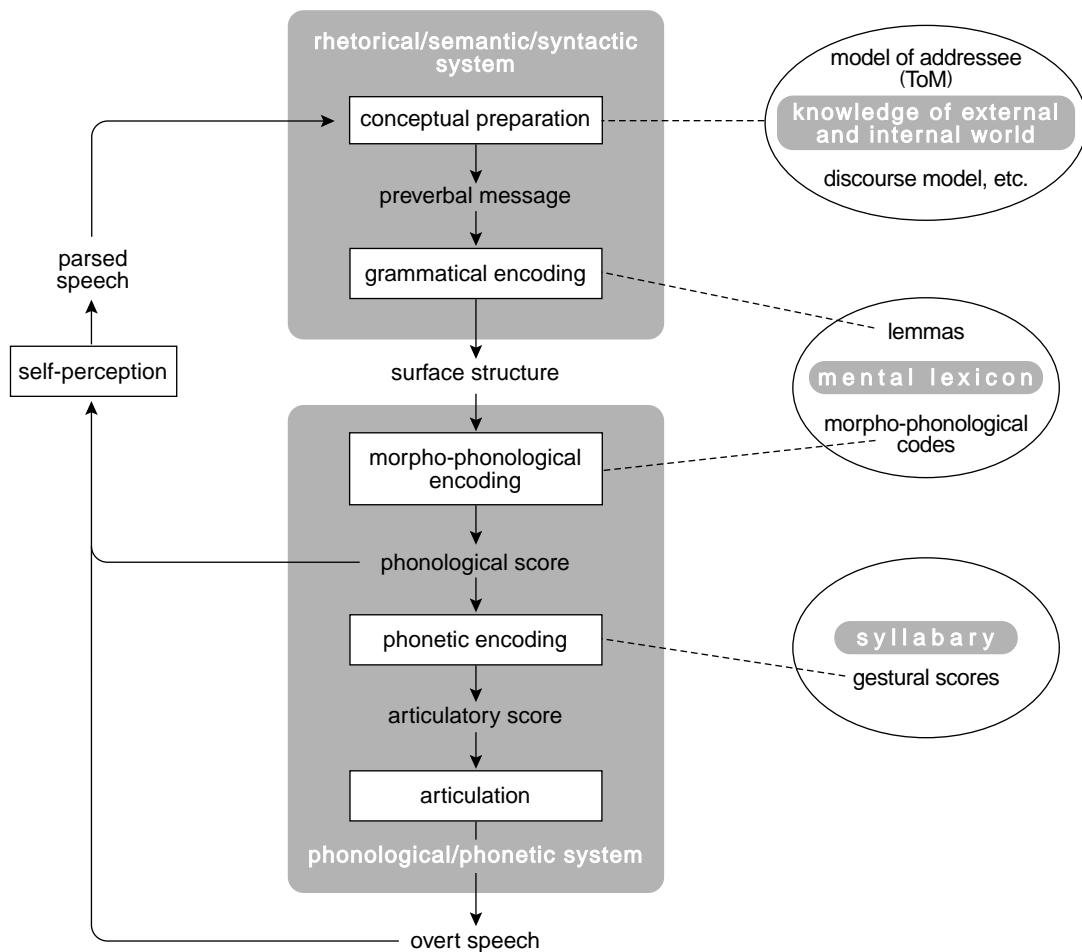

FIGURE 59.1 Framework of processing components involved in speech production. (From Levelt, 1999.)

achieved state of discourse, the attentional focus of the interlocutor, and so on (Clark, 1996). Conceptual preparation capitalizes on our “theory of mind” skills—the ability to estimate an interlocutor’s state of relevant beliefs and desires (Premack and Premack, 1995). All this is subsumed under *macroplanning* (Butterworth, 1980; Levelt, 1989). One important aspect of macroplanning is “linearization”—deciding what to say first, what to say next, etc. (Levelt, 1981). This involves both rhetorical decisions about how to guide the listener’s attention and efficient management of working memory.

There is, in addition, *microplanning*. To be expressible in language, a conceptual structure must be in a special, “propositional” format. Visual images, musical patterns, and motor images are typically in a different representational format. If they are to be expressed linguistically, they must be recoded. This recoding is flexible, and dependent on the communicative goals. The same visual image of a sheep and a goat juxtaposed can be expressed as “there is a sheep, and a goat to the right of it” or “there is a goat, and a sheep to the left of it” (and in

many other ways). This phenomenon, called *perspective taking*, is not limited to the recoding of visual representations (cf. Levelt, 1996; Clark, 1997). The terminal elements in the propositional format must be *lexical concepts*, concepts for which there are words in the language. The choice of lexical concept is an important aspect of perspective taking. There are always multiple ways to refer to the same entity: The *animal/dog/labrador frightened me* or *the interval/consonant/fifth is out of place here*. Perspective taking is ubiquitous in language production. As speakers, we are continuously mediating between visual, motor, person, etc., imagery systems and semantic systems of lexical concepts. This mediation is under the pressure of communicative effectiveness. It wouldn’t be surprising if conceptual preparation turns out to be a widely distributed cerebral affair.

GRAMMATICAL ENCODING The lexical concepts that are activated in constructing a message for expression trigger the retrieval of *lemmas* from the mental lexicon. These are syntactic words, characterized by a syntactic

frame. There is a lemma for each lexical concept and for all function words. Syntactic word frames specify, among other things, how semantic arguments in the message (such as theme or recipient) should be mapped onto syntactic functions (such as direct or indirect object). In *Sally gave Peter a bike*, the recipient of Sally's giving is Peter and the theme is a bike. The syntactic frame of *give* moves the corresponding lemmas into indirect and direct object position, respectively. The syntactic frames of selected lemmas (verbs, nouns, etc.) combine and recombine to build a syntactic pattern for the message as a whole, a "surface structure." Surface structures are *incrementally* created. As soon as a first lemma is selected, syntactic construction is initiated, and it keeps going as further lemmas become available. These processes are typically disturbed in agrammatic patients.

MORPHOPHONOLOGICAL ENCODING A first major step in the generation of the articulatory shape of an utterance involves the creation of phonological words and phrases and the generation of intonational phrases. A core process here is the retrieval of phonological codes. Once selected, a lemma activates the phonological codes of each of its morphemes. For instance, after selection of the noun lemma *postbox*, the codes for each of its morphemes *post* and *box* are activated: /pəʊst/, /bɒks/. Most neuroimaging work in word production involves monomorphemic words and hence reveals nothing about the production of complex morphology.

Accessing a word's or morpheme's phonological code is no trivial matter, neuropsychologically speaking. Anomic disorders, for instance, are often blockades of phonological access with preserved access to syntactic information. Badecker, Miozzo, and Zanuttini (1995), for instance, reported the case study of an Italian anomic patient who is unable to name any picture, but in all cases knows the gender of the target word. Gender is a syntactic word property, encoded in the lemma. Jescheniak and Levelt (1994) have shown that the "word-frequency effect" (i.e., picture naming is slower when the name is a low-frequency word than when it is a high-frequency word) emerges during the retrieval of a word's phonological code. It does not arise at the level of lemma selection. Clearly, there is a dedicated system involved in the storage and retrieval of phonological codes.

The primary use of phonological codes is the generation of syllabic structure. The domain of syllabification is the phonological word. Syllabification doesn't respect lexical boundaries. In the phrase *I understand it*, the syllabification becomes *I un-der-stan-dit*, where the last syllable (*dit*) straddles a lexical boundary; *understandit* is a single phonological word. Syllabification also depends on inflection—*un-der-stand*, *un-der-stands*, *un-der-*

stan-ding—it is a highly context-dependent process. Most probably, a word's syllabification is not stored in its phonological code. The incremental syllabification of phonological words in connected speech is an independent computational process (cf. Levelt, Roelofs, and Meyer, 1999, for a detailed theory of phonological word formation).

As the surface structure expands, the speaker also composes larger phonological units. One such unit is the *phonological phrase*. It is a metrical unit. It tends to start right after the lexical head of a surface phrase (i.e., right after the noun of a noun phrase, or right after the main verb in a verb phrase), and it leads up to include the next lexical head. Here is such a metrical grouping: *the fellow/that I sought/was standing/near the table/*. Within a phonological phrase, there is so-called nuclear stress on the lexical head word.

Phonological phrases combine into smaller or larger *intonational phrases*. These are sense units that are characterized by their intonation contour. The whole of the example sentence above can be cast as a single intonational phrase. Pitch movement will then lead up to the *nuclear tone*, which consists of a pitch accent on the first syllable of *table* (*ta-*), followed by a boundary tone on the last syllable of the phrase (*-ble*). Falling boundary tones suggest completion, whereas rising boundary tones invite continuation either on the part of the speaker or on the part of the interlocutor. The ultimate output of morphophonological encoding is called the *phonological score* (in analogy to a musical score).

PHONETIC ENCODING The incremental generation of metrically grouped and pitch-marked phonological syllables is closely followed by the generation of gestural patterns for these syllables in their larger context. It is largely unknown what kind of processing mechanism creates these gestural scores. The system must be generative in that speakers can produce syllables that they never produced before (in reading nonsense words for instance). Still, it appears from language statistics that speakers of English or Dutch do some 85% of their speaking with no more than 500 different syllables (out of more than 12,000 different syllables; cf. Schiller et al., 1996). In these languages, speakers hardly ever produce an entirely new syllable. Also, many languages (such as Mandarin Chinese) have no more than a few hundred different syllables. Hence, it is reasonable to assume that these highly overused articulatory routines are stored somewhere in the brain, and the premotor cortex is a good candidate (cf. Rizzolatti and Gentilucci, 1988). This repository of gestural scores is called the *mental syllabary* (Levelt, 1992). The generated gestural pattern for an utterance is called the *articulatory* or *gestural score*.

ARTICULATION Whatever the origin of the articulatory score, it is ultimately executed by the laryngeal and supralaryngeal systems. These are under the control of the larynx and face area of the somatosensory cortex, caudal midbrain structures, and cerebellum. Articulatory execution is quite flexible. The same articulatory target can often be realized in different ways. The system tends to minimize effort, given the prevailing physical contingencies. It is, for instance, possible to speak intelligibly with food or even a pipe in the mouth. Articulation is our most sophisticated motor system. It is normal to produce some 12 speech sounds (consonants, vowels) per second, and this involves control over some 100 different muscles. This masterpiece is achieved by concurrent, overlapping execution of articulatory gestures (Liberman, 1996).

SELF PERCEPTION, MONITORING, AND REPAIR Speakers are their own listeners. Whether listening to one's own speech or listening to somebody else's speech, the same superior temporal lobe structures are activated (McGuire, Silbersweig, and Frith, 1996, Price, Wise, et al., 1996). This feedback is one way for the speaker to exercise some degree of output control. For instance, we immediately adapt the loudness of our speech to the prevailing noise in our speech environment. We also tend to correct obvious or disturbing output errors or infelicities. This self-monitoring, however, is not based solely on the feedback of overt speech. We can also monitor our internal speech and catch an error before the word is (fully) pronounced (as in: *we can go straight to the ye-, to the orange node*, where the almost-error here is *yellow*). What is this internal speech? As Wheeldon and Levelt (1995) have experimentally argued, it's likely that what we monitor for in internal speech is the phonological score, i.e., the output of morphophonological encoding.

This bird's eye view of the speaker's functional organization provides us with the further layout of this chapter. We first discuss the many neuroimaging studies in word production. In that discussion, we are guided by a stage theory of word production, as diagrammed in figure 59.1. Following that, we turn to the few studies of grammatical encoding and to some studies of internal speech and self-monitoring.

Producing words: A task analysis

In neuroimaging studies of word production, we encounter a rich variety of tasks—verb generation, noun generation, picture naming, word reading, word repetition, generating words starting with a particular letter, and the like. The choice of experimental tasks and con-

trols demonstrates both inventiveness and ingenuity, but may also carry with it some degree of arbitrariness. Subtraction studies, in particular, are based on a difference logic that requires a componential analysis of the functional organization involved in the experimental and control tasks. It is rare, however, that such a componential analysis is independently performed and tested—say, by way of reaction time studies. Pending such task analyses, the present review can provide only a theoretical handle, presenting a componential analysis of normal word production based on the theoretical framework in figure 59.1. A fuller, comprehensive account of that functional word production theory can be found in Levelt, Roelofs, and Meyer (1999).

The left panel of figure 59.2 represents the components—the “core processes”—involved in word production, as derived from figure 59.1. As far as word production is concerned, the core aspect of conceptual preparation is to map some state of affairs onto a lexical concept. The state of affairs can be a perceptual image (as in picture naming), the image of an activity (as in verb generation), and so forth. In all cases we find perspective taking—a decision on the type of lexical concept that is apparently wanted in the experimental task. (For instance, one must decide whether to name an object by its basic level term, such as *dog* in normal picture naming, or to use a superordinate term, such as *animal* in a semantic categorization task.) The grammatical encoding aspect of word production is lemma access—selecting the appropriate syntactic word. It is at this step that the word's syntactic properties, such as gender, mass/count noun, syntactic argument structure, etc., become available. There are two major aspects to morphophonological encoding, now distinguished in figure 59.2. The first one, morphological encoding, provides access to the word's morphological structure and the phonological codes of each morpheme. For the monomorphemic words used in almost all neuroimaging studies, this stage is just accessing the word's phonological code. An important independent variable here, affecting just this stage, is word/morpheme frequency. The second one, phonological encoding proper, is the incremental construction of the phonological word and in particular the word's syllabification in context. This is probably the word representation figuring in internal speech. It may be (but need not be) the end stage in silent word generation tasks. The next component, phonetic encoding, provides a gestural or articulatory score for the word. It is likely that highly practiced syllabic motor routines are accessed at this stage. In the final stage of word production, the constructed or retrieved gestural score is executed by the articulatory apparatus, resulting in an overt acoustic signal, the spoken word. In all nonsilent word generation tasks

Tasks	(silent) Picture naming	(silent) Verb or Noun generation	(silent) Reading	(silent) Pseudoword reading	(silent) Generation from initial letters	(delayed) Word repetition
Lead-in Processes	visual object recognition	visual or auditory word recognition, visual imagery, retrieving associated actions from LTM, word association	visual word recognition	visual grapheme recognition, conversion of graphemic to phonological code	retrieving and "reading" orthographic word patterns some semantic processing	auditory word perception or audio- phonological parsing, (articulatory loop rehearsal)

FIGURE 59.2 Core processing stages in the production of words and the involvement of core and lead-in processes in various word production tasks. A check mark indicates involvement of the component process in the task. A check mark

there is auditory feedback, triggering the speaker's normal word perception system. But there is feedback in silent word generation too, probably from the level of phonological word encoding.

The subsequent columns of figure 59.2 present a tentative analysis of the various word production tasks reviewed in this chapter. In particular, these columns mark the core processing components that are probably involved in these tasks. This aspect of the task analysis is relatively straightforward (though not at all inviolable). Much more problematic is the analysis of what we call

in parentheses indicates that the component's involvement depends on details of the task. Phonetic encoding and articulation, for instance, are involved in overt, but not in silent word production tasks.

the task's "lead-in." Different tasks enter the componential structure depicted in the left panel at different levels. In picture naming, for instance, the task enters the componential hierarchy from the very top component, conceptual preparation. The lead-in process is visual object recognition, which provides an object percept as input to conceptual preparation. Compare this to pseudoword reading. Here the hierarchy is probably entered at the level of phonological encoding—there is no accessing of a syntactic word or of a word's phonological code, but there is syllabification. The lead-in process is visual

orthographic analysis, some kind of bottom-up grapheme-to-phoneme mapping, which provides the ordered pattern of phonemes as input to syllabification. These lead-in processes are the real bottleneck for neuroimaging studies in word production. They are usually easily invented but ill-understood; still, they always contribute essentially to the neuroimaging results. Without serious behavioral research, one can only speculate at the processes involved in most task lead-ins. The top row of the columns in figure 59.2 provides some hunches about the lead-in processes involved in the various neuroimaging studies of word production. Here, we discuss just seven of them.

Picture naming Here the lead-in process is visual object recognition. It is the best understood lead-in process. Still, many variables are to be controlled, including visual complexity, perspectival orientation of the object, color versus black-and-white, and, of course, object category. All core components of word production are involved in picture naming.

Verb generation This task also involves all core components of word production, but the lead-in process is ill-understood (cf. Indefrey, 1997). The subject sees or hears a noun, which triggers a visual or auditory word recognition process. If the noun is a concrete one, the subject will probably generate a visual image; and, under the perspective of the task, that image activates one or more associated actions in long-term memory. These, then, guide the further conceptual preparation. When the noun is abstract, long-term memory may be accessed without visual imagery. But there are possible shortcuts, too. A perceived noun may directly activate a verbal concept or even a verb lemma by sheer association, as in *knife-cut*.

Noun generation The typical task here is to present a semantic category, such as “jobs” or “tools” or “animals,” and the subject is asked to generate as many exemplars as possible. It is a so-called “word fluency” task. The lead-in process may involve something as complicated as an imaginary tour, such as mentally touring a zoo, or it may be a much lower-level process, such as word association. And the subject’s strategy may differ rather drastically for different semantic categories. But it is quite likely that, at least from lexical selection on, all core processes of word generation are involved.

Generating words from beginning letter(s) The lead-in process is quite enigmatic. The letter “a” is a preferred stimulus. Like most other letters, it does not represent a unique phoneme in English, and the task probably capi-

talizes on visual word imagery. We can apparently retrieve orthographic word patterns beginning with “a.” The same holds for so-called “stem completion”—transforming a word-beginning like “gre-” to its completed form “green.” These visually imaged patterns are then “read,” occasionally involving some semantic activation. From there on, we are back to the core process, somewhere beginning at morphological or phonological encoding.

Word repetition The subject repeats a heard word. The lead-in process involves auditory word recognition, at least to some extent. We can repeat words we don’t understand (and nonwords for that matter); hence it suffices to have the phonological parse of the word. From there, the core process can be triggered at the level of phonological encoding (we must syllabify the word). Still, the lead-in process may be a lot richer, involving activation of the full lexical concept. In delayed word repetition tasks, an “articulatory loop” is involved—the subject rehearses the word during the delay.

Word reading The lead-in process is visual word recognition, which is complicated enough by itself. The core process may start at the low level of phonological encoding, from the set of activated phonemes (the phonological route); or it may start all the way up from the activated lexical concept (the semantic route). The strategy may differ from subject to subject, even from word to word.

Pseudoword reading Here, only the phonological route is available after the visual lead-in process. Although nonwords can have morphology (as in “*Jabberwocky*”), that was never the case in the tasks reviewed here. Hence, phonological encoding is the first core process in a pseudoword reading task.

In the following we will, to the best of our abilities, acknowledge the components involved in both the experimental word production tasks and their controls. But given the present state of the art, this is not always possible.

Cerebral localizations for word production— A meta-analysis

Research on brain regions involved in word production has been carried out with a wide variety of techniques. Among these are the study of brain lesions, direct cortical electrical stimulation, cortical stimulation by means of implanted subdural electrode grids, recording and source localization of event-related electrical and magnetic cortical activity (ERP, MEG, subdural electrode grids, single-cell recordings), and measurement of re-

gional cerebral metabolic and blood flow changes (PET, fMRI). Clearly, these techniques have contributed to our present knowledge on the neural substrates of single word production in different ways. Take cortical stimulation for example. Usually applied in the context of impending surgical interventions, cortical stimulation has provided evidence on loci which, when temporarily inactivated, impair word production—i.e., loci that are in some way necessary for the production process. But this technique is applied only to locations where language-related sites are suspected and then only to the limited part of the cortex that is exposed. In contrast, PET and fMRI can, in principle, reveal all areas that are more strongly activated during word production—including areas that may not be essential to the process and/or those whose impairment leads to no detectable difference in performance. ERP and MEG have provided preliminary insights in the temporal course of cortical activations. The sources of event-related electrical or magnetic activations can be localized. There are, however, limitations inherent in the mathematical procedures involved, so that, at present, the spatial information provided by these methods is considered less reliable. Due to the nature of the signal, subcortical structures are largely invisible to electrophysiological methods.

The purpose of this section is to combine the evidence provided by all these techniques and to give an overview of the localization (and to some extent the temporal order) of cerebral activations during word production. Furthermore, we will try to identify the neural substrates of the different processing components laid out in the previous section. To this end, we analyze the data reported in a large number of studies according to the following heuristic principle: If, for a given processing component, there are subserving brain regions, then these regions should be found active in all experimental tasks sharing the processing component, whatever other processing components these tasks may comprise. In addition, the region(s) should not be active in experimental tasks that do not share the component.

This approach allows for the isolation of processing components between studies even if isolation within single studies is not possible due to the difficulty in controlling for lead-in processes. Nevertheless, four conditions must be met. First, the processing components must be independently defined, so that their absence or presence can be evaluated for every experiment by applying the same criteria (which may differ from the author's criteria). Second, the task and control conditions must be heterogeneous enough across different experiments to ensure that a specific processing component is the only shared component. Third, the task and control condi-

tions must be heterogeneous enough across different experiments to ensure that for every processing component there is a different set of tasks that share the component. Fourth, the data base must be large, comprising enough experiments for a reliable identification of activations typically found for the different tasks. For word production these requirements seem to be sufficiently met, considering that word production tasks have been among the most frequently applied language tasks in neurocognitive research.

PROCEDURE We analyzed the cerebral localization data from 58 word production experiments (table 59.1). Our focus was on the core process of word production; thus, we excluded experiments reporting enhanced cerebral activations during word production tasks relative to control tasks that comprised most or all of the word production process—reading aloud, for example (Petersen et al., 1989; Raichle et al., 1994; Buckner, Raichle, and Petersen, 1995; Snyder et al., 1995; Fiez et al., 1996; Abdullaev and Posner, 1997), or object naming (Martin et al., 1995). Nor did our approach allow for inclusion of experiments or task comparisons focusing on the relative strengths of components of the word production process—comparisons of reading regularly spelled versus irregularly spelled words, for example (Herbster et al., 1997). Activations of these two tasks relative to baseline, however, were included. It was assumed throughout that the reported activation foci reflected true increases during the tasks rather than decreases during the baseline conditions.

Combining data from different techniques made it necessary to find a common term for cerebral localizations observed in relation to certain tasks. Since the majority of experiments employed PET or fMRI, we will use the terms “activations” or “activated areas,” extending that usage to EEG and MEG sources and to sites where cortical stimulation or lesions interfere with certain functions. We are aware that, for the latter case, one can at best infer that such locations are “active” in normal functioning.

The double reference system for anatomical localizations adopted here was used in order to capture data on the localization of cerebral activations stemming from methods with different resolution. On a gross level, comparable to a high degree of filtering, the reported loci were coded in a descriptive reference system dividing the cerebral lobes into two or three rostrocaudal or mediolateral segments of roughly equal size. Activations of cingulate, insula, and cerebellum were only differentiated in left and right. The segment labels were defined in terms of Talairach coordinates as given in table 59.2 (top).

TABLE 59.1
Overview of experiments included in the word production data set

Task	Authors, methods, control conditions			
Picture naming aloud	Ojemann (1983) Cortical/thalamic stimulation	Ojemann et al. (1989) Cortical stimulation	Schäffler et al. (1993) Cortical stimulation	Crone et al. (1994) Subdural grid
	Haglund et al. (1994) Cortical stimulation	Salmelin et al. (1994) MEG	Abdullaev & Melnichuk (1995) Single-cell recordings, blank screen	
	Bookheimer et al. (1995) PET, nonsense drawings	Damasio et al. (1996) Lesion data	Damasio et al. (1996) PET, “faces,” up/down	Levelt et al. (1998) MEG

Word repetition aloud	Petersen et al. (1989) PET, silent listening	Howard et al. (1992) PET, reversed words, “crime”		Crone et al. (1994) Subdural grid
	Price et al. (1996b) PET, rest	Gordon et al. (1997) Cortical stimulation		
Pseudoword repetition silent	Warburton et al. (1996) PET, rest			

More detailed anatomical references were additionally coded on a finer level in terms of gyri and subcortical structures following Talairach and Tournoux (1988). At this level, cingulate, insular, and cerebellar activations were further differentiated descriptively (table 59.2, bottom). In this way, it was possible to capture the fact that a PET activation focus reported as, for example, left inferior temporal gyrus, BA 37, would be consistent with electrophysiological data reporting a posterior temporal source localization or with patient data reporting a left posterior temporal lesion. Note that the sum of activations on the detailed level does not equal the number of activations on the gross level. A location, for example, that was reported as posterior temporal would be marked only on the gross level. Conversely, two posterior temporal locations in the superior and middle temporal gyrus were marked as such on the detailed level but only once on the gross level.

The studies included in this meta-analysis were not given any weights reflecting reliability differences due to design or size. This means that a certain degree of overlap of activations between studies was considered meaningful, but should not be interpreted as statistically significant. Nonetheless, the notion of “meaningfulness” was not totally arbitrary, but based on the following quasi-statistical estimate: At the gross level of description, there were on average 6.5 activation sites reported per experiment. Given that on this level of description

there were 28 regions of interest, any particular region had a chance of less than one-fourth to be reported as activated if reports were randomly distributed over regions. At the finer level of description, the average number of reported activation sites per experiment was 8.8 and there were 104 regions of interest; thus each had a chance of less than one-tenth to be reported as activated. Assuming these probabilities, the chance level for a region to be reported as activated in a number of studies was given by a binomial distribution. We rejected the possibility that the agreement of reports about a certain region was coincidental if the chance level was less than 10%. At the finer level of description, this corresponded to minimally two reported activations for regions covered by less than six experiments, minimally three reported activations for regions covered by six to eleven experiments, and so forth (4 out of 12–18; 5 out of 19–25; 6 out of 26–32). Note that for regions covered by many experiments a relatively smaller number of positive reports was required to be above chance (comparable to the fact that getting a 6 five times with ten dice throws is less likely than getting one 6 with two dice throws). But this criterion does not mean that atypical findings of activations in any single study are necessarily coincidental. In most cases, the number of experiments *not* reporting activations was not sufficient to consider a region as inactive at the chosen error probability level. Rare observations do not,

TABLE 59.2
Definition of descriptive anatomical labels

Subdivisions of cortical lobes at grosser level of description			
Frontal		Temporal	
Anterior	$y > 34$	Anterior	$y > -7$
Posterior	$34 \geq y \geq 0$	Mid	$-7 \geq y \geq -38$
Motor (approx.)	$y < 0$	Posterior	$y < -38$
Parietal		Occipital	
Sensory (approx.)	$y > -23$	Medial	$x \leq 25 $
Anterior	$-23 \geq y \geq -48$	Lateral	$x > 25 $
Posterior	$y < -48$		
Subdivisions of cingulum, insula, and cerebellum at finer level of description			
Cingulum		Insula	
Anterior	$y > 12$	Anterior	$y > 0$

Posterior	$y < -24$		
Cerebellum			
Medial	$x \leq 20 $		
Lateral	$x > 20 $		

therefore, exclude the possibility that a region is active. They may, for example, reflect smaller activations that are only detectable with refined techniques or better scanning devices.

A second, related point is that the nature of the data does not allow for an interpretation in terms of relative strengths of activations of certain areas. It is known that parameters such as item duration and frequency strongly influence the resulting pattern of activations (Price et al., 1994; Price, Moore, and Frackowiak, 1996). It is thus possible that areas are more frequently found active in some tasks, because their "typical" item durations and frequencies are higher or lower than in other tasks. It seems wise not to overinterpret the data, given that there is a considerable variability of these parameters across the studies of our data base; also, the interactions of these parameters with other experimental factors are largely unknown.

LEAD-IN PROCESSES According to our task analysis, nonshared activations in picture naming and word generation (table 59.3, first two columns) cannot be related to the core process of word production. The two tasks differ not only with respect to their lead-in processes but also with respect to the processes of phonetic encoding and articulation, given that word generation was performed silently in all experiments of the data set, whereas the majority of picture naming experiments involved overt articulation with silent control tasks (see table 59.1). Hence, to study the lead-in processes of picture naming, we must take into account activations that were specific for picture naming when compared to word generation and at the same time were not specific for overt (in contrast to silent) naming in general (table 59.3, last two columns). Although such lead-in activations were fairly numerous, we cover only the two most conspicuous sets here.

Six regions were reported as activated during word generation but rarely activated during picture naming: the left anterior superior frontal gyrus, the right anterior insula, the right mid superior and middle temporal gyri, the left caudate nucleus, and the right thalamus. While activations of the left anterior frontal and middle temporal gyri, right anterior insula, and left caudate seem to be specifically related to lead-in processes of word generation (see also Fiez, Raichle, and Petersen, 1996), the case is different for the right mid superior temporal gyrus and the right thalamus, which are also found in word reading.

Ten regions were activated during picture naming but not or only rarely during word generation: the left anterior insula, the left posterior inferior temporal and fusiform gyri, the medial occipital lobe bilaterally, the right

caudate nucleus, the left midbrain, and the medial and right lateral cerebellum (see, however, Fiez and Raichle, 1997, for evidence on right cerebellar activations in word generation when directly compared with word reading or picture naming). Five of these—the left anterior insula, the left posterior fusiform gyrus, the left and right medial occipital lobe, and the right medial cerebellum—were also found active in word reading, suggesting an involvement in visual processing, the principal lead-in component of picture naming and reading. Taking into account that activations of the posterior fusiform gyrus or the insula were not reported for pseudoword reading, it seems that these two areas may play a role at later visual processing stages, such as the retrieval of visual word forms or object patterns (cf. Sergent, Ohta, and MacDonald, 1992). In contrast, medial occipital activations observed during word and pseudoword reading are demonstrably due to the processing of nonlinguistic visual features of word-like stimuli, such as string length (Beauregard et al., 1997; Indefrey et al., 1997).

THE CORE PROCESS OF WORD PRODUCTION According to our task analysis, picture naming and word generation are the two tasks that include all components of word production. The set of regions reported as activated for both tasks (table 59.3, first two columns) can be considered as being related to the core process of word production up to and including phonological encoding. This word production network is strictly left-lateralized, and consists of the posterior inferior frontal gyrus (Broca's area), the mid superior and middle temporal gyri, the posterior superior and middle temporal gyri (Wernicke's area), and the left thalamus.

By taking into account further tasks that enter the word production process at different stages, we now attempt to identify the subprocesses to which these regions are particularly sensitive.

Conceptual preparation and lexical selection The activation of a lexical concept and the subsequent selection of the corresponding lemma are processes that are shared by picture naming and word generation but not necessarily by word reading. The synopsis of reported results yielded one area within the word production network—the mid segment of the left middle temporal gyrus—that has been found activated during picture naming and word generation, but less so during word reading. This area is the best candidate for a neural correlate of conceptual and/or lexical selection processes in word production. The mid part of the left middle temporal gyrus has been found as part of a "common semantic system" in a study (Vandenberghe et al., 1996) involving word and object stimuli. This finding is compatible with a role of this region in conceptual

*The number of activations reported for a region is given in proportion to the number of studies covering it. Relative cell frequencies exceeding the error probability threshold of $p < .1$ are printed in bold. Data were collapsed with respect to overt versus silent responses in the last two columns. Aloud tasks with aloud control conditions are grouped with silent tasks.

Key: Except for SMA (= supplementary motor area), the abbreviations of gyri and subcortical structures follow Talairach and Tournoux (1988): GFs, GFm, GFi = superior, middle, and inferior frontal gyrus; GFd = medial frontal gyrus; GO = orbital gyri; GR = gyrus rectus; Gs = gyrus subcallosus; GPrC = precentral gyrus; GTs, GTm, GTi = superior, middle, and inferior temporal gyrus; GF = fusiform gyrus; Gh = parahippocampal gyrus; GL = lingual gyrus; GpoC = postcentral gyrus; LPs, LPi = superior and inferior parietal lobule; PCu = precuneus; Gsm = supramarginal gyrus; Ga = angular gyrus; Sca = calcarine sulcus; Cu = cuneus; GOs, GOm, GOi = superior, middle, and inferior occipital gyri; NL = lenticular nucleus.

processing. It should, however, be kept in mind that the activation of a lexical concept for word production is only one very specific conceptual process among many other conceptual-semantic processes. It is, more precisely, to be distinguished from the semantically guided search processes in word generation (possibly subserved by anterior frontal regions), as well as from prelinguistic conceptual processes involved in object recognition and categorization [possibly subserved by the ventral temporal lobe and a heterogeneous set of category-specific regions (cf. Martin et al., 1995, 1996; Damasio et al., 1996; Beauregard et al., 1997)]. As far as the core process of word production is concerned, these conceptual processes are to be considered as lead-in processes.

Phonological code retrieval Lexical word form retrieval takes place in picture naming, word generation, and word reading, but not in pseudoword reading. This pattern is found in the reports on activations of the left posterior superior and middle temporal gyri, i.e., Wernicke's area, and the left thalamus. The posterior superior temporal lobe has also been found active during word comprehension (Price, Wise, et al., 1996). It is thus conceivable that a common store of lexical word form representations is accessed in word production and comprehension.

Phonological encoding All tasks, including word repetition and pseudoword reading, involve the production of phonological words. Neural structures subserving this process should consequently be found active throughout. No region fulfills this requirement perfectly, but the left posterior inferior frontal gyrus (Broca's area) and the left mid superior temporal gyrus come very close. Both regions just miss our criterion for a meaningful number of activations in tasks for which there are only few studies in the data set (word repetition, word generation from initial letters). Cabeza and Nyberg (1997) reviewed one repetition and two reading aloud experiments with Broca's area as the only active region in common. According to our task analysis, the only common processing component was indeed phonological encoding.

Broca's area has been observed to be active not only during explicit but also during implicit processing of pseudowords (performing a feature detection task; Frith et al., 1995; Price, Wise, and Frackowiak, 1996). The left mid superior temporal gyrus, however, was not found active in these studies, which may indicate a functional difference between the two areas within nonlexical phonological processing.

Broca's area is, furthermore, known to be activated in tasks involving phonological processing in language comprehension (Démonet et al., 1992, 1996; Zatorre et al., 1992; Fiez and Raichle, 1997). The common denom-

inator of these observations and the activation of Broca's area in language production seems to be that this region is a nonlexical phonological processor.

Price and Friston (1997) presented a statistical method—conjunction analysis—to isolate common processing components between different experiments. They used this method to identify a processing component, which they called phonological retrieval, across four word production experiments. The following areas were reported to be related to this processing component: the left posterior basal temporal lobe BA 37 (this area corresponds to the fusiform gyrus in our terminology), the left frontal operculum, the left thalamus, and the midline cerebellum. Given that “phonological retrieval” according to our analysis corresponds to the two processing stages of phonological code retrieval and phonological encoding, the observed activations of the left thalamus and the left frontal operculum are in good agreement with the results we obtained here on the basis of a large number of reported experiments. The other two areas according to our analysis subserve a high-level visual lead-in process and the articulatory process. Price and Friston (1997) assume these processes to be shared by the control conditions (viewing objects or strings of false fonts and saying “yes” to every stimulus), leaving only “phonological retrieval” as the common component of all task-control contrasts. It should, however, be noted that this assumption holds only if the contributions of these task components are constant in the active task and the baseline task. The authors themselves point out that this core assumption of the cognitive subtraction paradigm is problematic. Visual and motor-related activations have been observed to be modulated (e.g., by attention or response selection) in active relative to passive tasks (Friston et al., 1996; see also Shulman et al., 1997, for medial cerebellar activations in controlled motor response tasks). It is therefore not excluded that activations related to visual and articulatory processing were equally enhanced in all four active tasks and consequently not filtered out by the conjunction statistics.

Phonetic encoding and articulation Activations related to the production of the abstract articulatory program and its execution should be found in tasks with overt pronunciation and silent control conditions, but not in silent tasks or in tasks where articulation has been controlled for (table 59.3, last two columns). All aloud tasks with silent controls led to activations of primary motor and sensory areas, i.e., the right and left ventral (and, to some extent, dorsal) precentral gyri and the right and left ventral postcentral gyri; but in the group of silent or controlled aloud tasks, such activations were rarely reported. This finding was expected, since these areas are

known to be involved in the sensorimotor aspects of articulation. Hence, it provides independent validation for our analysis procedure. It can also be concluded that output control conditions such as saying the same word to every stimulus cancel out these sensorimotor activations effectively.

Further regions typically found in aloud but not in silent tasks were the left anterior superior temporal gyrus, the right SMA, and the left and medial cerebellum. The dissociation in cerebellar activity, with left and medial parts being closely linked to motor output, confirms an observation by Shulman and colleagues (1997); it is also discussed in a comprehensive review of cerebellar activations by Fiez and Raichle (1997).

Our survey shows a complex pattern of reports on left anterior temporal and SMA activations. Both regions are related to overt pronunciation, but seem to be task-sensitive as well. While the temporal area is most frequently reported in overt picture naming, SMA activations (left and right) seem to be rare in this task. Also, SMA activations, though more frequent for aloud tasks, are observed to some extent in silent tasks as well. The latter is not restricted to silent word production, but is also found in tasks involving verbal working memory or nonverbal imagination of movements (for a discussion, see Fiez and Raichle, 1997). It may be concluded that the SMA is in some complex way related to motor planning and imagination of articulation. Given that the instructions in what we have designated silent tasks ranged from mere “viewing” to “thinking” to silent “mouthing” of responses, it is not difficult to understand that the SMA involvement may vary to a great extent between tasks.

SUMMARY The word production network that has been identified on the basis of a substantial number of experiments makes sense. It is largely identical with the set of regions found to be necessary for picture naming in direct cortical stimulation studies. Given that these comprised but a minority of the experiments analyzed and furthermore concentrated on a single task, this is not a trivial result. It means that the neuroimaging studies, despite their heterogeneity of methods and tasks, captured the essential processes of word production. It also means that the cerebral structures subserving these processes can be successfully distinguished from the large number of cerebral activations related to task-specific and experiment-specific processes by an appropriate meta-analysis procedure. On the other hand, neither the network as a whole nor any single region was found activated in all experiments. There are a number of reasons for this. First, weaker activations may have been overlooked or not reported. In general, the statistical thresh-

olds applied in neuroimaging experiments tend to be conservative; moreover, some authors may have focused on robust findings, applying very strict statistical thresholds that rendered minor activations insignificant. There also was a tendency toward fewer activations in older studies, where the technology could not reliably detect as many activations. Second, although we focused on experiments with low-level control conditions, so that the word production process itself would not be obscured, we could not confidently eliminate this obscuring in all cases. Stereotype overt responses (for instance, a “yes” response on all trials) may be retrieved from an articulatory buffer, but may also be normally produced (as is the case with meaningful response alternatives, such as saying “up” or “down” depending on the orientation of the stimulus object in the baseline task)—thereby taking away at least part of the activations due to core word production processes. Considering these points, it would have been misleading to apply the above heuristic principle to every single experiment rather than to sets of experiments using similar tasks, as we have done here.

The time course of word production

TIME WINDOWS FOR COMPONENT PROCESSES Every processing stage of word production takes time. Furthermore, as the above analysis suggests, cortical areas involved in word production are specialists for certain processing components. Activations in these regions should, therefore, have temporal properties that are compatible with the durations of the different processing stages. Table 59.4 summarizes the small number of studies that, to date, have provided timing information related to cortical areas involved in word production. We compare these data with estimates for the processing stages in picture naming given by Levelt and colleagues (1998) based on work by Thorpe, Fize, and Marlot (1996), Levelt and colleagues (1991), Roelofs (1997), Wheeldon and Levelt (1995), and Van Turennout, Hagoort, and Brown (1997, 1998).

It is estimated that visual and conceptual processing are accomplished within the first 150 ms, and lexical selection within 275 ms from picture onset. As identified in the previous section, the corresponding cortical sites were the medial occipital lobe (bilaterally), the left medial posterior temporal lobe for visual processing, and the mid segment of the left middle temporal gyrus for conceptual preparation and lexical selection. The time windows given for occipital activations in table 59.4 are in good agreement with what is assumed for early visual processing. Inferior posterior temporal activations during reading also seem to occur

TABLE 59.4
Time course of word production in relation to anatomical regions*

*Time intervals are given in milliseconds; additional anatomical information is given in parentheses. Ga = angular gyrus; Gsm = supramarginal gyrus; GTs, GTm = superior, middle temporal gyrus; GFi = inferior frontal gyrus.

in this time window (Salmelin et al., 1996). Instead of the expected middle temporal activation site, however, both Salmelin and colleagues (1994) and Levelt and colleagues (1998) identified dipoles in posterior parietal

regions, which have not been found active in PET studies.

Lexical phonological code retrieval and phonological encoding are estimated to take place between 275 and

400 ms. The corresponding cortical sites identified above were the left posterior superior and middle temporal gyri for accessing the form code, as well as the left posterior inferior frontal gyrus and the left mid superior temporal gyrus for phonological encoding. The time windows given in table 59.4 clearly support an involvement of Wernicke's area in word form retrieval. Further support comes from a study by Kuriki and colleagues (1996) reporting a time window of 210–410 ms in this region during a phonological matching task on syllabograms. The situation is less clear for phonological encoding, where both supporting and disagreeing time windows have been found for Broca's area and the mid segment of the left superior temporal lobe. The available data on the time course of word production thus support the localization studies with respect to lead-in processes and word form access. They are consistent with respect to phonological encoding, but raise doubt with respect to the cortical sites related to conceptual preparation and lemma access in word production.

INTEGRATING SPATIAL AND TEMPORAL INFORMATION Taking into account both the results of the previous section and the present data on the time course of word production, the following (tentative) picture of the spatial and temporal flow of activation in word production has emerged: In picture naming and probably also in word generation from visual stimuli (see Abdullaev and Posner, 1997) visual and conceptual lead-in processes involving occipital, ventrotemporal, and anterior frontal regions converge within 275 ms from stimulus onset on a lexical concept to be expressed. In addition, the best-fitting lexical item is selected within this period. The middle part of the left middle temporal gyrus may be involved in this conceptually driven lexical selection process. Within the following 125 ms, the activation spreads to Wernicke's area, where the lexically stored phonological code of the word is retrieved, and this information is relayed anteriorly to Broca's area and/or the left mid superior temporal lobe for post-lexical phonological encoding. Within another 200 ms, the resulting phonological word is phonetically encoded (with possible contributions of SMA and cerebellum to this or additional motor planning processes) and sensorimotor areas involved in articulation become active.

Syntactic production

Research on the neural correlates of syntactic processing has mainly concentrated on syntactic comprehension. Regions in and around Broca's area have been most frequently identified as being related to syntactic processing (Stowe et al., 1994; Indefrey et al., 1996;

Just et al., 1996; Stromswold et al., 1996). Caplan, Hildebrandt, and Makris (1996), on the other hand, did not find a significant difference in syntactic comprehension of agrammatic patients between anterior and posterior sylvian lesion sites in a thorough study involving a range of syntactic constructions. Just and colleagues (1996), too, found Wernicke's area (as well as the right-sided homologs of Broca's and Wernicke's area) to be sensitive to syntactic complexity. Two studies (Mazoyer et al., 1993; Dronkers et al., 1999) suggested a role for the left anterior superior temporal lobe in syntactic processing. The pseudoword sentence repetition task of Indefrey and colleagues (1996) comprised a syntactic production component in addition to syntactic parsing, and the resulting activation focus was more rostrally located (border of Broca's area and the adjacent middle frontal gyrus, BA 9) than the foci identified in pure comprehension tasks. Direct electrical stimulation of a similar site was found by Ojemann (1983) to interfere with the grammatically correct repetition of sentences. In the latter study, however, a number of perisylvian stimulation sites yielded the same effect, so that at present there is no real evidence for cortical areas specifically subserving syntactic production.

Self-monitoring

Self-monitoring (see figure 59.1) involves an *external loop*, taking as input the acoustic speech signal of the speaker's own voice, and an *internal loop*, taking as input the phonological score—i.e., the output of phonological encoding. The most economical assumption is that both loops enter the processing pathway that is used for normal speech comprehension (Levelt, 1989).

EXTERNAL LOOP There is evidence that hearing one's own voice while speaking induces the same temporal lobe activations as listening to someone else's voice (McGuire, Silbersweig, and Frith, 1996; Price, Wise, et al., 1996). McGuire, Silbersweig, and Frith, furthermore, were able to induce additional bilateral superior temporal activations by distorting the subjects' feedback of their own voices or presenting the subjects with alien feedback while they spoke. These results show that just as in listening to other people's speech (Démonet et al., 1992; Zatorre et al., 1992) attentional modulation of the activity of the temporal cortices in self-monitoring is possible.

INTERNAL LOOP McGuire and colleagues (1996) also provided some evidence that internal monitoring, too, makes use of a cortical area involved in speech

perception—more precisely, the left posterior superior temporal lobe. This area showed stronger activation (together with motor areas) when subjects imagined hearing another person's voice than when they spoke silently to themselves. It is not implausible that the observed blood flow increase was due to an attentional modulation of internal self-monitoring, although other explanations are possible as well.

Conclusion

Speaking involves substantially more than merely producing words. The recent neuroscience literature on speech production reviewed in this chapter is limited owing to its emphasis on word production. But this may well be a transient state of affairs. After all, the wealth of data that enabled the present meta-analysis derives from no more than a decade or so of neuroimaging research. We have an emerging picture now of the cerebral network that underlies the production of words. A crucial ingredient of this meta-analysis is the explicit, detailed functional theory of word production. It provided us with the framework for a componential task analysis and with time frame estimates for the component processes. No doubt, the same approach, applied to other aspects of speaking, will eventually lead to similar progress.

60 The Study of Prelexical and Lexical Processes in Comprehension: Psycholinguistics and Functional Neuroimaging

DENNIS NORRIS AND RICHARD WISE

ABSTRACT Here we review the functional neuroimaging literature relating to prelexical auditory and visual processes. We relate neuroimaging work to current psychological models of word perception and discuss some of the problems inherent in the use of the standard subtractive method in this area. The signal returned by cortex associated with speech perception is large, which makes the techniques sensitive to the study of prelexical processes. The major regions involved are primary and association auditory and visual cortices of both hemispheres. The results of the neuroimaging work are shown to be consistent with other studies using ERP and MEG.

Functional neuroimaging of prelexical and lexical processes: Introduction

Over the past decade, a number of functional neuroimaging papers have been published on language activation studies. Studies with positron emission tomography (PET) have predominated, although the number of functional magnetic resonance imaging (fMRI) studies is increasing. Both techniques rely on the rise in regional cerebral blood flow (rCBF) that accompanies a net increase in local synaptic activity. PET activation studies are based on the accumulation of regional tissue counts after the intravenous bolus infusion of radiolabeled water (H_2^{15}O) (Mazziotta et al., 1985). The signal in the most commonly used fMRI technique, the BOLD (blood oxygenation level-dependent) image contrast, originates from an increase in the oxyhemoglobin:deoxyhemoglobin ratio on the venous side of the local intravascular compartment of the tissue being sampled; a transient increase in local synaptic activity is associated

with an increase in rCBF in excess of the rise in oxygen consumption, with greater oxygen saturation of venous blood (Thulborn, 1998). Emphasizing the source of the signal in functional neuroimaging acknowledges one of the two major limitations of these techniques in the study of prelexical (and other) processes: Changes in nutrient blood flow occur over many hundreds of milliseconds whereas many of the underlying electrochemical events are complete in tens of milliseconds. The limited temporal resolution of functional neuroimaging (thousands of milliseconds with fMRI; and, with PET, neural transients have to be summed over 15–30 seconds) is also confounded by limited spatial resolution. Even the theoretical resolving power of MRI (1–2 mm) may be misleading, as the signal comes from the intravascular compartment, possibly a little distant from the local neural system under investigation. The signal from PET, the tissue concentration of H_2^{15}O , more directly signals where events are occurring, but the physics associated with this technique, and the smoothing required in image analysis, means that it is difficult to resolve separate peaks of activation that are less than 5 mm apart. It is possible to overcome the problem of temporal resolution when studying some functional systems, such as visual attention, by combining neuroimaging and electrophysiological techniques to relate a component of an event-related potential to an activated region on a PET/fMRI image (Heinze et al., 1994). The spatial resolution results in an “activation” that is the net change in activity of many millions of synapses.

Using modern PET cameras it is possible to do a 12–16 scan activation study in under two hours with a radiation exposure acceptable to radiation advisory committees. An fMRI study of comparable duration, with no exposure to ionizing radiation, typically allows ten times the number of measurements, although fMRI has its

RICHARD WISE Medical Research Council Cyclotron Unit and Imperial College School of Medicine, Hammersmith Hospital, London

own problems: relatively low sensitivity, susceptibility to movement artifacts because of the higher spatial resolution, and the sheer volume of data that is acquired.

Although the limitations of functional neuroimaging restrict the ability to address many issues of interest to psychologists and psycholinguists, relating behavioral observations to human brain structure and physiology is one of the more important bridges to cross in cognitive neuroscience. This chapter reviews currently available data on sublexical and lexical processing of both spoken and written language and considers the success (or otherwise) of functional neuroimaging and electrophysiological studies when addressing psychological theories of prelexical processing. The brain regions involved are the primary and association auditory and visual cortices. One of the challenges in such studies has been to demonstrate lateralized activations, as it soon became evident from the earliest PET studies that the perception of heard and seen words produced very symmetrical activations in auditory and visual cortices, respectively, in terms of both peak and extent.

The subtractive method and language

The standard functional neuroimaging paradigm is the subtractive method. Ideally, two tasks are chosen which differ only in their demands on a single process. Subtraction of images obtained during the performance of both tasks identifies the brain area(s) responsible for that process. Effective application of this method needs a good cognitive model of the processes under study and a detailed analysis of the tasks. An a priori hypothesis about how the cognitive model might be implemented neurally will also considerably enhance the interpretation of the results.

Even if all of these prerequisites were met, any attempt to apply the subtractive method to language processing to isolate a specific stage of linguistic processing faces considerable technical and theoretical problems. The early stages of language processing are highly automatic and overlearned, so it is difficult or impossible to devise tasks that make listeners or readers process input to one level and no further. Consider the problem of trying to force spoken input to be processed up to, but not including the lexical level. The obvious comparison here would be between words and nonwords. However, all current theories of spoken word recognition assume that nonwords will activate a number of partially matching candidate words to some level. The best we can do is hope that nonwords produce less lexical activation than words. To compound the problem, once input is processed to the lexical level, it is likely also to be processed semantically and possibly even interpretively. So, words

will also activate semantic areas while nonwords will activate lexical areas (at least). Unfortunately, subtracting word and nonword processing is not going to have the desired effect of isolating areas responsible for a specifically lexical level of processing. This may explain why at least two PET studies have failed to find any differences between words and nonlexical stimuli. Hirano and colleagues (1997) compared normal Japanese sentences with the same sentences played in reverse. Fiez and colleagues (1996) compared words with nonwords. Neither study found differences.

Models

The central focus of cognitive models of both spoken and written word recognition has been the lexical access process itself. Theories like the interactive activation models of McClelland and Rumelhart (1981) and Grainger and Jacobs (1996) in the visual domain, and TRACE (McClelland and Elman, 1986), Shortlist (Norris, 1994), and Cohort (Marslen-Wilson and Welsh, 1978) in the spoken domain have all concentrated on explaining how orthographic or phonological representations make contact with lexical representations. These models differ in important respects (for example, TRACE is interactive while Shortlist is bottom-up); however, with the exception of the Cohort model, each of these theories assumes that lexical access involves a process of competition between simultaneously activated lexical candidates. Visual or spoken input results in the activation of a number of matching, or partially matching, lexical candidates that compete with each other by means of lateral inhibition until a single winning candidate emerges. In the case of spoken input, the competition process also performs the essential task of parsing continuous input (in which word boundaries are generally not marked) into a sequence of words. The principle of competition now has extensive empirical support in the case of both spoken (e.g., McQueen, Norris, and Cutler, 1994) and visual input (e.g., Andrews, 1989; Forster and Taft, 1994). So, there is widespread agreement among models in terms of the broad characterization of lexical access. There is much less of a consensus about prelexical processing. In reading there is unanimity over the importance of letters in prelexical processing, but much less certainty about the nature of any intermediate orthographic representations (e.g., Raap, 1992; Perea and Carreiras, 1998, on syllables) or whether phonological representations play a role in lexical access (e.g., van Orden, 1987; Lesch and Pollatsek, 1998).

In speech, most models largely follow a standard linguistic hierarchy and have stages of acoustic, phonetic, phonemic, and phonological analysis, although not all

models have all stages. For example, TRACE adopts a very conventional linguistic approach with levels corresponding to features and phonemes. However, TRACE has no phonological representation of metrical structure such as mora, syllable, or foot. Shortlist (Norris et al., 1997) assumes that metrical information must be available, but it too does not specify an explicit prelexical stage of phonological processing. In fact, although Shortlist accesses the lexicon via phonemic representations, this is really a matter of implementational convenience rather than a result of a commitment to a phonemic level of representation.

The existence of a strictly phonemic level of processing has been questioned in both the linguistic and the psycholinguistic literature. Some linguistic frameworks, such as underspecification theory (cf. Archangeli, 1984; Kiparski, 1985; Pulleyblank, 1983), have no role for the a phonemic level of representation. In psychology, Lahiri and Marslen-Wilson (1991) have argued that the work usually attributed to a phonemic level can be accomplished by a level of featural representation instead. Marslen-Wilson and Warren (1994) have argued that phonemic and phonological representations are constructed postlexically (but see Norris, McQueen, and Cutler, *in press*). Other authors have argued that the syllable is the most important prelexical level of representation (Mehler, 1981) and that phonemes play only a secondary role. It should be clear from this that psycholinguists cannot yet offer a definitive cognitive account of prelexical processes and representations. Indeed, determining exactly what those processes and representations are is one of the central goals of current psycholinguistic research.

Implementation

Even when we seem to be asking very simple questions about large-scale architectural issues, questions of implementation can significantly alter the kind of conclusions we might draw from an imaging study. Consider the problem of identifying areas responsible for auditory and “phonological” processing. In the imaging literature this has been approached by comparing speech (in either active or passive listening tasks) with “nonspeech” stimuli such as tones (Demonet et al., 1992, 1994; Binder et al., 1996), noise bursts (Zatorre et al., 1992), or signal-correlated noise (Mummary et al., *in press*). The assumption behind these studies is that the nonspeech stimuli will not activate the areas responsible for phonological processing. But both “nonspeech” and speech should be fully processed by acoustic areas. The output from these areas must then be passed on to the “phonological” areas. Unless the auditory areas are designed to prevent nonspeech signals from being passed on to the

phonological system, the phonological system will receive at least some input. Intuitively, of course, it seems that speech should engage the phonological areas much more than nonspeech. But this needn’t be the case, certainly not for the early stages of phonological or phonetic processing. It is only once some part of the speech processing system has tried, and then failed, to categorize the input into a form appropriate for further speech analysis that subsequent areas will not receive an input. As we all know, trying to do something we can’t do can be much harder than doing something we can do. We can see this kind of problem in a very extreme form in the Auditory Image Model proposed by Patterson, Allerhand, and Giguere (1995). In this model of early auditory processing there is a component designed to deal with periodic signals. When given periodic signals, it produces a clean stabilized image of the input, revealing the fine structure of the periodic signal. With aperiodic signals, this stage produces noise. Depending on the details of the neural implementation, this component could do less work when analyzing the periodic signals it is specialized for than when attempting to analyze aperiodic signals. However, we should bear in mind that it is not at all clear how a hemodynamic response on a scan relates to apparent task “difficulty.” Furthermore, even connectionist models are not attempts to faithfully capture the architecture of inhibitory and excitatory neural subsystems. For example, inhibitory and excitatory synapses both consume energy, and a “deactivation” (reduction in local blood flow) on an image reflects a net reduction of synaptic activity in a region with many polysynaptic pathways.

At least some of these issues might be profitably approached by correlational methods. Instead of contrasting speech and nonspeech, one could vary the strength of a particular speech property (while keeping the signal relatively unchanged acoustically). Therefore, a subject may be required to listen to acoustic or visual signals that vary along one of a number of dimensions, and the changing response of a brain region correlated with this varying input. This technique is being applied in terms of the rate of presentation of stimuli, or by using psychological variables such as word imaginability or frequency, and the same strategy can be used for the physical properties of an input signal. These techniques can explore the natural processing of the stimuli without the need to make A – B subtractions between two more or less metalinguistic tasks.

Tasks

The processing of heard words is a function of primary and association auditory cortex; and similarly, seen words activate striate and prestriate cortex (figure 60.1A,B). One

FIGURE 60.1 The first three columns show the orthogonal projections of the brain created by the image data analysis program (SPM96—Wellcome Department of Cognitive Neurology) (Friston et al., 1995a,b): Left = axial; middle = sagittal; right = coronal. The orientation (left/right/anterior) is shown on the bottom row of images. In the fourth column are activations displayed on selected slices of the MRI template available in SPM96. The threshold was set at $p < .05$, corrected for analysis of the whole brain volume. (A) Twelve normal subjects listening to single words contrasted with seeing the same words. There are bilateral, symmetrical, extensive DLTC activations. In the coronal MRI slice, the activations are seen to run mediolaterally along Heschl's gyrus. (B) As (A), but now seeing single words has been contrasted with hearing words. There are bilateral, symmetrical, extensive posterior striate/prestriate activations. In the axial MRI slice, the activations are seen to extend toward the occipitotemporal junction. As only foveal vision is used to read single words, striate cortex subserving parafoveal and peripheral retinal vision has not been activated. (C) Three experiments with six normal subjects in each (eighteen subjects in all), in which seen and heard word imagability was varied. Words of higher imagability produced greater activity in left ventral temporal cortex (the fusiform gyrus). Both the peak and extent of this imagability effect were much smaller than observed in (A) and (B). It is a feature of all functional imaging experiments on lexical semantic processes, in a temporal lobe region thought to be a major site for the representations of semantic knowledge, that the signal is small relative to prelexical processes.

noticeable feature is that they return a strong signal, even when the stimuli are “passively” perceived. Although many neuroimaging studies to date have been concerned with lexical–semantic processes, the signal obtained in ventral temporal regions is smaller, both in terms of extent and peak activity (figure 60.1C). Therefore, anatomically constrained, strongly activated prelexical systems are potentially easier to study with functional neuroimaging than lexical–semantic and syntactic language systems.

Imaging studies have generally adopted standard psycholinguistic tasks. For example, a popular task in imaging studies has been phoneme monitoring, in which listeners are required to press a button when they hear a particular phoneme in the input. This task is employed as a way of engaging “phonological¹” processing, and has been compared with passive listening (Zatorre et al., 1992, 1996) or monitoring for changes in the pitch of pure tones (Demonet et al., 1992, 1994). However, from a psycholinguistic standpoint, the most significant observation about the phoneme monitoring task is that it can be performed only by listeners who have been taught to read an alphabetic script (Read et al., 1986). Illiterates, for example, are unable to perform phoneme monitoring, or most other tasks involving explicit segmentation. In other words, phoneme monitoring makes cognitive demands over and above those required by normal speech perception. This fact has long been recognized

by psycholinguists and is an important feature of the most recent psychological model of phoneme monitoring and phonetic judgments (Norris, McQueen, and Cutler, in press).

Interpretation of phoneme monitoring studies therefore has to be tempered with the possibility that the results may tell us as much about the structures involved in performing a particular metalinguistic task as they do about speech perception itself. However, it can still be a valuable cognitive task as, in almost all psycholinguistic accounts, phoneme monitoring is assumed to tap into the products of the normal speech recognition process at some level. However, the use of phoneme monitoring to tap into speech processing is logically very different from its use in an imaging study if the intention is that the task should engage normal phonemic/phonetic processing. If we find that a particular brain area activates only when performing an explicit metalinguistic task, like phoneme monitoring, we have no evidence that this area is directly involved in the normal phonetic or phonological processing of speech. The area could be responsible solely for interrogating the normal speech recognition systems in order to generate a response in this particular task.

Interestingly, much of the data showing specifically left-hemisphere activation comes from a comparison of metalinguistic, or active, tasks, with passive listening (Zatorre et al., 1992; Demonet et al., 1994). There tends to be more left-hemisphere activation with active listening. A similar pattern also emerges in a MEG study (Poeppel et al., 1996) where active discrimination of a voicing contrast ($/b\alpha\epsilon/$ and $/d\alpha\epsilon/$ vs. $/p\alpha\epsilon/$ and $/t\alpha\epsilon/$) led to an increase in M100 amplitude in the left hemisphere and a decrease in the right as compared to a passive listening condition.

Note that one interpretation of the imaging data on phoneme monitoring and other active listening tasks is suggested by Fiez and colleagues (1995). Possibly, the increased attentional demands of these tasks lead to increased activation in normal speech processing areas relative to passive listening tasks. This would be consistent with ERP and MEG studies of auditory processing that have found increased activation in the auditory areas contralateral to the attended ear (Näätänen, 1990; Woldorff, Hackley, and Hillyard, 1991; Woldorff and Hillyard, 1991; Woldorff et al., 1993). However, any cognitive model still needs to account for the behavior of illiterates and assume that there is some process responsible for the metalinguistic phonemic judgment, which should presumably result in brain activation itself.

We can see some evidence of activation of other brain areas involved in phoneme monitoring in the studies by Zatorre and colleagues (1992, 1996), who found activation of visual cortex, and by Demonet and

colleagues (1994), who found activation of the left fusiform gyrus. Possibly, this is related to the fact that phoneme monitoring is known to be influenced by orthographic factors (Dijkstra, Roeloffs, and Fieuws, 1995; see also Donnenwerth-Nolan, Tanenhaus, and Seidenberg, 1981; Seidenberg and Tanenhaus, 1979). However, perhaps the most worrying feature of studies comparing active and passive listening tasks is that passive listening is more than likely to involve completely normal phonetic/phonemic processing. What these studies may well have done is to design tasks that factor out normal speech processing and highlight the brain areas involved specifically in the metalinguistic tasks. Indeed, Zatorre and co-workers (1996) acknowledge that passive listening would engage an important automatic component of phonetic processing and may involve essentially full semantic processing.

Acoustic-phonetic and phonemic processes

It is hard to know exactly where, if at all, to place a boundary between acoustic and phonetic processing. One could define phonetic processing as being concerned with extraction of specifically linguistic features such as place and manner of articulation of consonants. Acoustic processing would then be defined as those characteristics, such as loudness and frequency, that are not of direct linguistic significance. Architecturally, however, there is no a priori reason why a particular phonetic feature should not be computed by the same brain areas responsible for acoustic analysis rather than some later, purely linguistic, stage. Indeed, many animal studies show that primary auditory cortex is sensitive to complex acoustic features that, in humans, might well be considered to be phonetic. A great deal of work has shown that the primary auditory cortex of a number of different species produces a change in response at voice onset times analogous to the human category boundary between voiced and unvoiced consonants (e.g., Eggermont, 1995; Sinex, McDonald, and Mott, 1991; Stein-schneider et al., 1995). Recently, Ohl and Scheich (1997) have shown that the primary auditory cortex of gerbils is organized in a manner that is sensitive to the difference between the first and second formant frequencies of vowels, an important factor in human classification of vowels (Peterson and Barney, 1952). In a nonlinguistic species, presumably, these features must be acoustic, and not phonetic. In humans, too, we should probably not be surprised to find such features processed by auditory cortex rather than some later, specifically linguistic, stage of phonetic or phonemic processing. As we will see later, the idea that much phonetically significant processing takes place in primary auditory cortex also re-

ceives support from many human studies, especially those using ERP and MEG.

Although studies using PET and fMRI have been directed at identifying particular stages of phonetic or phonological processing, other work has addressed more detailed questions about differences in processing within individual stages of linguistic analysis. For example, how does processing differ between vowels and consonants or even between different vowels? Much of this work has used ERP, MEG, or even direct cortical stimulation.

Boatman and colleagues (1997) examined the effects of direct cortical electrical interference on consonant and vowel discrimination using implanted subdural electrode arrays. With electrical interference, consonant discrimination was impaired at one electrode site in each patient on the superior temporal gyrus of the lateral left perisylvian cortex. Without electrical interference, consonant-vowel discrimination was intact and vowel and tone discrimination remained relatively intact when tested with electrical interference at the same site. Rather interestingly, the crucial sites were located differently in different patients. This suggests that within these anatomical areas there are individual differences in the details of functional localization. Such differences could reflect either innate structural differences or different outcomes of a learning process.

Given the considerable crosslinguistic variation in phonemic inventories, both in the number and the nature of the phonemic categories, learning must play some role in the establishment of phonemic categories. Using both ERPs and magnetoencephalographic recordings, Näätänen and colleagues (1997) compared processing of vowels by Finnish and Estonian listeners. They measured both the electrical (MMN) and the magnetic mismatch negativity (MMNM or magnetic mismatch field: MMF) response to a set of four vowels. For the Estonian listeners, the four vowels all corresponded to prototypical Estonian vowels. For the Finnish listeners, only three of the four vowels corresponded to prototypical vowels in their language. Listeners were presented with the phoneme /e/ and, infrequently, with one of the other three vowels to elicit a mismatch response. For the Finnish listeners, there was a much larger mismatch negativity when the infrequent vowel was the Finnish /ö/ than when it was a nonprototypical vowel (the Estonian /õ/), even though the /õ/ is actually more dissimilar to the /e/ phoneme in terms of formant structure. Estonian listeners showed large mismatch responses to both /ö/ and /õ/. In contrast to this phonemically determined response in the MMN amplitude, MMN latency was a function solely of the degree of acoustic dissimilarity of the infrequent stimulus. For the Finnish listeners the magnetic mismatch neg-

activity (MMNM) response was larger in the left hemisphere than the right when the infrequent phoneme was a Finnish prototype vowel. In the left hemisphere the MMNM originated in the auditory cortex, but in the right hemisphere the responses were not strong enough to reliably localize the source of the response.

Other studies have examined the neuromagnetic responses N100m (or N1m or M100), P200m, and SF (sustained field), which are the magnetic analogs of the electrical responses N100, P200, and SP (sustained potential). By combining MEG and MRI, the source of the N100m evoked by pure tones is known to lie on the surface of the Heschl gyri, which include primary auditory cortex (Pantev et al., 1990).

Poeppel and colleagues (1997) measured the N100m response to vowels varying in pitch and to pure tones. The N100m dipole localizations in supratemporal auditory cortex were the same for vowels and pure tones. They found no differences in N100m amplitude due to vowel type or pitch. However, response latency was influenced by vowel type but not by pitch. Response latency thus appears to be sensitive to vowel type, but not to pitch. This suggests that processing in supratemporal auditory cortex is already extracting pitch-invariant phonetic properties. Aulanko and colleagues (1993) used the syllables /bæ/ and /gæ/ in a mismatch paradigm where the syllables were synthesized on 16 different pitches. They also found that MMNM responses (localized to the supratemporal auditory cortex) were maintained despite the variations in pitch. In another MEG study Diesch and co-workers (1996) looked at dipole localizations of N100m and SF deflection in response to the German vowels /a/, /æ/, /u/, /i/, and /o/. Here, too, there was considerable intersubject variability in the locations of the sources, but the ordering of the distances between N100m and SF equivalent dipole locations was much more systematic and could be interpreted as reflecting distances in vowel space or featural representations of the vowels.

Listening to words

In imaging studies, listening to words without an explicit task demand produces strong activations in bilateral dorso-lateral temporal cortex (DLTC) that is both extensive and symmetrical (figure 60.1A; see Petersen et al., 1988; Wise et al., 1991; Binder et al., 1994). This symmetry seems to be at odds with the “dominance” of the left hemisphere for heard word perception; psychophysical and psychological evidence suggests that the temporal resolution required for analysis of the rapid frequency transitions associated with consonants (occurring over < 50 ms) is de-

pendent on a neural system lateralized to the left hemisphere (for review, see Fitch, Miller, and Tallal, 1997).

It has been suggested that the more constant acoustic features of words, such as vowel sounds, might be analyzed by the right hemisphere (Studdert-Kennedy and Shankweiler, 1970). However, Lund and colleagues (1986) found that left-hemisphere lesions, mainly located in Wernicke’s area, tended to disrupt vowel perception whereas none of their patients with lesions in the corresponding area of the right hemisphere had perceptual problems.

Speech perception is robust, even when the sounds are distorted in a variety of ways (e.g., Miller, 1951; Plomp and Mimpen, 1979). No single cue seems to determine the comprehensibility of speech and a listener uses a range of acoustic features, which may explain why word deafness (agnosia for speech in the absence of aphasia) usually occurs only after bilateral lesions of dorso-lateral temporal cortex (DLTC) (Buchman et al., 1986; Polster and Rose, 1998). Therefore, it is to be expected that acoustic processing of speech input should involve the DLTC of both hemispheres.

Using a parametric design, where the rate of hearing single words was varied between 0 and 90 words per minute (wpm), one PET study distinguished regions in left and right DLTC that showed an approximately linear relationship between activity and rate from a single region, in the left posterior superior temporal gyrus (postDLTC), where activity was close to maximal at 10 wpm (Price et al., 1992). This study set a precedent for inferring a difference in processing from the shape of the activity-input curve. It is true that another study—one using fMRI to investigate left and right primary auditory cortex (PAC) and postDLTC—did not reproduce this original result (Dhankar et al., 1997); but this may be because the preeminent interest in left postDLTC (the core of “classic” Wernicke’s area) may be misplaced. It has become apparent from a number of imaging studies that the DLTC anterior to PAC (midDLTC) is central to the acoustic and phonological processing of heard words. Three studies (Zatorre et al., 1992; Demonet et al., 1992, 1994) have contrasted phoneme monitoring in syllables or nonwords with decisions on the pitch of stimuli (syllables or tones). All three studies identified bilateral mid-DLTC, although activation on the left was greater than on the right for the detection of speech sounds. This emphasis on midDLTC, and not postDLTC, in the prelexical processing of words is also evident in the fMRI study of Binder and co-workers (1996).

Although neurologists generally attribute a central role in speech perception to Wernicke’s area, support for this from functional neuroimaging is mixed. Fiez and colleagues (1996) and Petersen and colleagues

(1988, 1989) all found activation of Wernicke's area (Brodmann's area 22 close to the temporoparietal junction) when comparing passive word listening with fixation. Interestingly, Fiez and co-workers (1996) also found no differences between words and nonwords. They acknowledge that this could be due to phonological analysis, lexical activation, or perhaps to phonological storage. However, Fiez and colleagues (1995) and Zatorre and colleagues (1992) failed to find temporoparietal activation, even though Fiez's group examined both active and passive listening tasks, and did find temporoparietal activation when comparing listening to tones with a fixation task. Binder and co-workers (1996) demonstrated that activation in the left planum temporale was similar for tones and words, and there was greater activity for tones in an explicit task on the stimuli. However, as we have discussed, a response to non-linguistic stimuli does not preclude the possibility that a region is specialized for a linguistic purpose.

As noted, midDLTC asymmetry in studies using phoneme monitoring may reflect modulation of DLTC activity by attentional processes rather than "dominance" of the left temporal lobe in prelexical processing. A contrast of "passive" listening to words with listening to signal-correlated noise (SCN—acoustically complex sounds without the periodicity of words) demonstrated symmetry of DLTC function: The rates of hearing both words and SCN correlated with cerebral activity in PAC and adjacent periauditory cortex of both hemispheres, and correlations specific to words were located symmetrically in left and right midDLTC (Mummery et al., in press). Frontal activations were absent. Although it cannot be inferred that symmetrical PET activations imply symmetrical processing functions, these results do support single-case studies suggesting that the DLTC of both hemispheres is involved in the acoustic *and* phonological processing of words (Praamstra et al., 1991).

Another, more natural demand on auditory attention is made when a subject has to "stream out" a particular source of speech in a noisy environment, the usual example cited being the cocktail party. Auditory stream segregation (Bregman, 1989) is open to investigation with functional neuroimaging, although no studies, to the authors' knowledge, have as yet been published. However, the effects of another source of speech sounds, one's own voice, has been investigated. Attention to one's own articulated output will be variable, depending on how carefully a speaker wishes to use on-line, post-articulatory self-monitoring in the detection and correction of a wide range of potential speech errors (Levelt, 1989). It is assumed that the same processors that analyze the speech of others are used to monitor one's own voice. This has been confirmed by a number of PET studies (Price et al.,

1996; McGuire et al., 1996). However, studies in humans and monkeys with single-cell recordings have demonstrated modulation of temporal cortical activity by phonation/articulation (Müller-Preuss and Ploog, 1981; Creutzfeldt, Ojemann, and Lettich, 1989). Figure 60.2 demonstrates a comparable result at the local systems level in a PET study that investigated variable rates of listening and repeating in normal subjects. When listening, each subject heard word doublets, with each word heard a second time after an interval of 500 ms. Therefore, during both the listening and repeating conditions the subjects heard the same word twice, although in the former both words of each pair came via headphones while in the latter the second word of each pair was the subject's own voice. During repeating, particularly at high rates, the articulated output must be discriminated from the stimuli so as not to interfere with the acoustic and phonological analysis of the latter. When activity in left periauditory cortex was plotted against the rate of hearing words during both the listening and repeating tasks, there was some separation of the curves (figure 60.2A); but when plotted against the rate of hearing the stimuli alone (figure 60.2B), there was no evidence of modulation (i.e., suppression) of the response to the stimuli by articulation. The small additional contribution of own voice to activity may be explained by a general reduction of attention to this source of sound, and by the attenuation of the higher tones of own voice because of transmission to the middle ear by bone conduction. In contrast, the same activity-rate plots show suppression of activity in response to the stimuli in left midDLTC by articulation (figure 60.2C and D), the physiological expression of auditory streaming during repeating. Post-articulatory self-monitoring is likely to be minimal when repeating single words. Manipulating the complexity of speech output could be used to test the hypothesis that varying the demand on post-articulatory self-monitoring correlates with activity in left midDLTC, which would confirm modulation of activity in this region by attention towards one's own speech output.

A further study has assessed the modulation of DLTC activity by articulation (Paus et al., 1996). Subjects whispered syllables at rates varying from 30 to 150 per minute (any residual sound from the subject's larynx was masked by white noise), and increasing motor activity was associated with an increase in activity in the left planum temporale and left posterior perisylvian cortex, attributed to motor-to-sensory discharges. Such discharges may allow listeners to rapidly segregate their own articulations from the simultaneous speech of others.

So far, two activity-rate responses have been recorded in DLTC in response to hearing single words. The first reaches a maximum at relatively low rates of

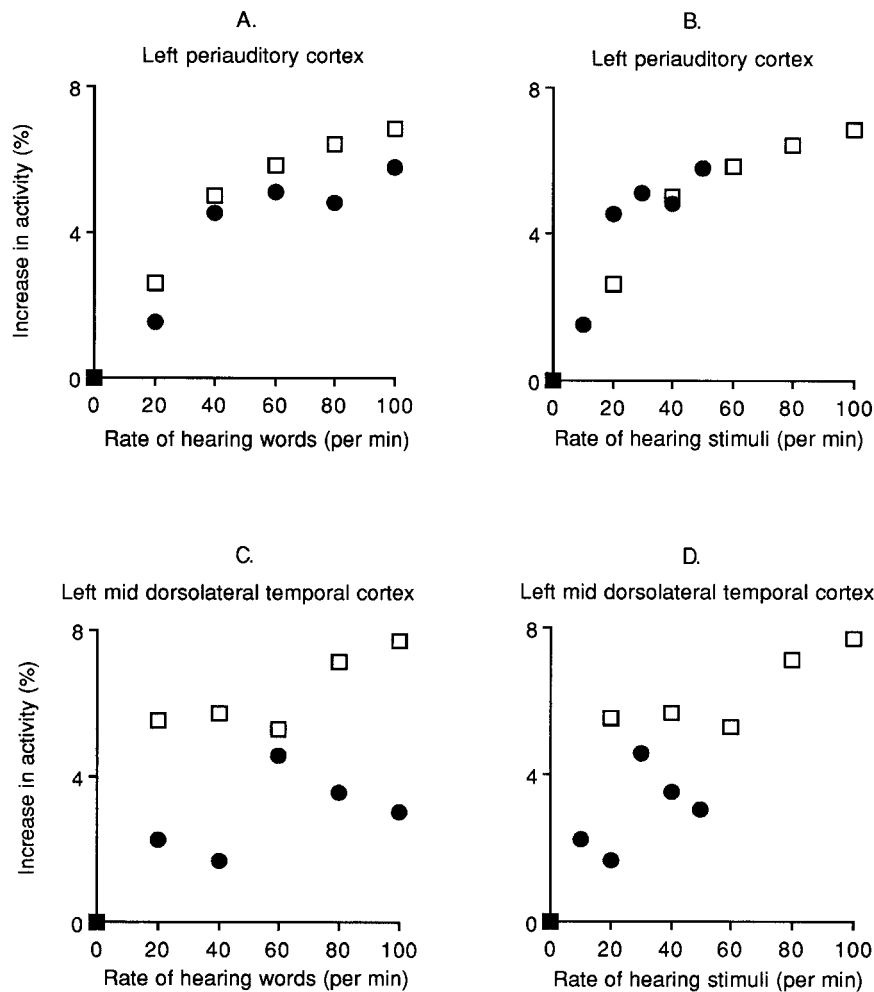

FIGURE 60.2 (A) The percentage increase of activity (regional cerebral blood flow) plotted against the rate of hearing words during listening (open squares) and repeating (closed circles) in left periauditory cortex. The baseline activity (closed square) was measured when the subjects were expecting to hear stimuli but received none during the period of data acquisition. During the listening task the words were heard as doublets (each word was repeated after a delay of 500 ms); during repeating the stimulus words were only heard once, but the rate of hearing words was the same as that in the listening task, as the subjects heard their articulated responses. The response curves showed activity to be a little less during repeating than listening, but this did not reach significance. (B) The same plot as (A), but the ordinate is the rate of hearing stimuli; therefore,

during repeating the range is half that during repeating, as hearing own voice is excluded in this analysis. Activity in response to external input is approximately matched in the two conditions—the slightly greater activity associated with repeating reflects a small contribution from own voice. (C) The same plot as in (A), but for left midDLTC. There was a significantly lower activity ($p < .05$, corrected for analysis of the whole brain volume) for repeating compared to listening. (D) The same plot as (B): Activity was modulated (suppressed) by articulation, so that net synaptic activity was reduced even in response to the external stimuli. This demonstrates an overall reduction of responsiveness of this local neural system, interpreted as a “focusing” of prelexical processing on the stimuli and not the articulated output.

word presentation and there is little increase in activity for higher rates of hearing words (figure 60.3); this was the response reported by Price and colleagues (1992) in left postSTG and approximately describes the behavior of left midDLTC in figure 60.2C. The second is one of increasing, if progressively diminishing, activity up to a rate of ~90–100 wpm, seen in left periauditory cortex in figure 60.2A; but at higher rates activity diminishes (figure 60.3), as observed by Dhankar and colleagues (1997). Cortical responses are dependent on both the

local neural architecture and those of subcortical structures that directly or indirectly (via polysynaptic pathways) project to DLTC. All neural systems have a refractory period after receiving an input, during which time further input cannot be processed. The curves in figure 60.3 originate from the behavior of the local neural subsystem plus or minus its interaction with other local (cortical and subcortical) subsystems. The shape of these, and other, response curves in DLTC could be subjected to signal modeling; although these models

FIGURE 60.3 A representation of the two types of activity-rate responses (open squares and closed circles) in DLTC so far reported in the literature.

will inevitably be simplifications, analyses of response curves is potentially a powerful way of observing neuromodulation and rapidly or slowly evolving neural plasticity. Thus, instead of subtraction analysis between observations made in two behavioral states to decide whether a local system is “on” or “off,” parametric designs with a varying input could be used to observe changes in the response curves of cortical and subcortical subsystems: for example, when the subject is or is not attending to the stimuli; during the course of learning/habituating to an executive task on the stimuli; and, translating into clinical research, during the course of recovery following a stroke, either occurring naturally or as the result of a particular therapy, in perilesional or remote cortex. The relatively high signal:noise ratio in functional images of the prelexical systems of DLTC make these good candidates for such research.

Seeing words: PET and fMRI studies

It has been known for more than a century that normal subjects can recognize single words as fast as single letters (Cattell, 1886). Therefore, the letters of a written word are perceived in parallel, and are not processed serially. The neuropsychological literature explains the alexia accompanying left occipital lesions in terms of impaired letter form discrimination, parallel letter identification, whole word form recognition, or visual attentional processes (for review, see Behrmann, Plaut, and Nelson, in press). The resulting “pure alexia” is associated with an increase in reaction time as the number of letters in a word increases (the word length effect).

Acuity in discerning a word’s constituent letters is dependent on foveal vision, which extends 1° to either side of fixation. Acuity in parafoveal vision, extending 5° to either side of fixation, rapidly declines with greater distance from fixation. Nevertheless, vision from this part of the retina provides important information about the overall shape and length of words (Rayner and Bertera, 1979). It has been determined that the spatial extent of a subject’s perceptual span during reading is asymmetric; it covers only 3–4 characters to the left but 12–15 characters to the right for a left-to-right reader (McConkie and Rayner, 1975), with presumably the opposite asymmetry for readers of Arabic, Farsese, and Hebrew. There is also a temporal component, with the duration of fixation on an individual word within a text lasting ~250 ms. A saccade, ending 7–9 characters to the right, moves the fixation point to the viewing point of the next word. In this way, text information is acquired rapidly, without discontinuities and the need for regressive saccades to fill in perceptual gaps.

Reduced right foveal/parafoveal visual information impairs text reading (“hemianopic” alexia; Zihl, 1995), and eye movement recordings have shown this to be due to disorganization of the spatial and temporal components of the perceptual span: Saccades may be too short or long, with frequent regressive saccades to fill in perceptual gaps. Text reading speed correlates with the number of degrees of sparing of the 5° of right foveal/parafoveal vision.

It is probable that there is no clear clinical division between the psychophysicists’ “hemianopic” alexia and the neuropsychologists’ “pure” alexia, and it is varying proportions of impairments in perceptual and temporal span, letter identification, and attentional processes that result in the slow reading of any particular patient. As both conditions accompany left occipital infarcts, the exact distribution of the lesion must affect one of two prelexical neural systems involved in perceiving text: one responsible for letter and whole word identification, and the other for rightward-directed attention (for European languages) controlling reading saccades. Functional neuroimaging studies have shown that the perception of letter strings and words activate posterior striate cortex (the receptive field for foveal vision) and prestriate cortex (Petersen et al., 1990; Rumsey et al., 1997; Price, Wise, and Frackowiak, 1996). As observed with auditory cortex, there is no evidence for asymmetry, although only left occipital lesions result in alexia. However, global alexia, which includes an inability to recognize single letters, usually occurs only when a left occipital lesion is accompanied by disconnection of right striate/prestriate cortex from the mirror regions on the left (Binder and Mohr, 1992). The presence of a complete, macular-

left

right

FIGURE 60.4 Activations coregistered onto axial MRI slices from the SPM96 template (the coordinate marks are in red). (A) Viewing single words, as in figure 60.1B. (B) Reading across horizontal word arrays (3 and 5 words) contrasted with viewing single words at the same rate, coregistered onto an MRI axial image 16 mm dorsal to the image in (A). This subtraction reveals the activation in the representation of right

parafoveal space in the left striate cortex, demonstrating the way that visual attention during text reading modulates activity in V1. (C) The same behavioral contrast as in (B), but 55 mm dorsal to the plane depicted in (B). This shows bilateral PPC and right FEF activations associated with the planning and generation of forward saccades during reading across horizontal arrays of words.

splitting hemianopia (with no visual information about letter/word form reaching the left striate cortex) does not preclude the ability to read single words; therefore, orthographic information can be processed in the right occipital lobe sufficient to support reading once the information is transferred to the left hemisphere via the corpus callosum.

The neural system for letter and word identification is shown in figures 60.1B and 60.4A. It has been shown that activity in these regions increases with increasing rate or duration of seeing single words (Price, Moore, and Frackowiak, 1996). Petersen and co-workers (1990) demonstrated that most of this cortex responded similarly to words, letter strings, and letter-like symbols, with the exception of a region in left prestriate cortex which responded only to words and pronounceable nonwords; they concluded that this was the location of the visual whole word form system. Subsequently, in a study of different design, Howard and colleagues (1992) located the word form system in the left posterior temporal lobe. This sharp phrenological distinction, on the basis of contrasts on observations made during two behavioral conditions, may be misleading, and it is unlikely that the more central “black boxes” of information processing models of language are represented as anatomically discrete cortical regions; realization of vi-

sual word form is perhaps better viewed as a distributed system between left prestriate and left posterior temporal cortex.

The neural system involved in word identification by controlling attention and eye movements across text is shown in figure 60.4B,C. This involves left striate cortex (V1, in the depth of the calcarine sulcus) receiving information from right parafoveal visual space (for left-to-right readers) (figure 60.4B), and posterior parietal cortex (PPC) and the frontal eye fields (FEF, right >> left) (figure 60.4C). Activity in these regions is not affected by the rate of presentation of single words, but is apparent when contrasting reading across horizontal arrays of words with reading single words presented at the same rate. PPC and FEF activations are apparent in other studies that have investigated directed visual attention (Corbetta, 1998). The parafoveal V1 activation is consistent with visual attention’s being directed to the right of fixation when reading text left-to-right, and is a demonstration that visual attentional processes, at least during text reading, may modulate activity at the level of primary visual cortex. This is in contrast to the combined PET and event-related potential studies which have suggested that attention directed toward objects in visual space normally acts at the level of prestriate cortex (for example, see Heinze et al., 1994).

Conclusions

Much of the functional neuroimaging of language has been involved with responses in multimodal association cortex, which has on occasion been bedeviled by inconsistency of results across studies and debates about whether activations directly reflect language processing itself or represent a parallel process, such as working memory, involved in the performance of the tasks being used. Prelexical processes return stronger signals, and manipulating any one of a number of the physical properties of seen or heard verbal input, with or without the explicit attention of the subject, is an approach that has yet to be fully exploited. One of the more interesting applications will be to show changes in physiological responses over a series of scans in the same individual, particularly in relation to clinical questions directed at the processes underlying stroke recovery and post surgical adaptations to a cochlear implant (Okazawa et al., 1996).

NOTE

1. Note that in the imaging literature the term "phonological" is used to cover a far broader range of processes than simply the phonological component of spoken word recognition. In general, imaging studies of phonological processing have examined a range of tasks involving the manipulation and storage of phonological representations. Very little of this work can claim to have identified specifically linguistic areas of phonological processing (see Poeppel, 1996, for a critique of this work). The choice of tasks in this work often makes it difficult to relate imaging studies to standard distinctions in either the cognitive or linguistic literature.

61 Postlexical Integration Processes in Language Comprehension: Evidence from Brain-Imaging Research

COLIN M. BROWN, PETER HAGOORT, AND MARTA KUTAS

ABSTRACT Language comprehension requires the activation, coordination, and integration of different kinds of linguistic knowledge. This chapter focuses on the processing of syntactic and semantic information during sentence comprehension, and reviews research using event-related brain potentials (ERPs), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). The ERP data provide evidence for a number of qualitatively distinct components that can be linked to distinct aspects of language understanding. In particular, the separation of meaning and structure in language is associated with different ERP profiles, providing a basic neurobiological constraint for models of comprehension. PET and fMRI research on sentence-level processing is at present quite limited. The data clearly implicate the left perisylvian area as critical for syntactic processing, as well as for aspects of higher-order semantic processing. The emerging picture indicates that sets of areas need to be distinguished, each with its own relative specialization.

In this chapter we discuss evidence from cognitive neuroscience research on sentence comprehension, focusing on syntactic and semantic integration processes. The integration of information is a central feature of such higher cognitive functions as language, where we are obliged to deal with a steady stream of a multitude of information types. Understanding a written or spoken sentence requires bringing together different kinds of linguistic and nonlinguistic knowledge, each of which provides an essential ingredient for comprehension. One of the core tasks that faces us, then, is to construct an integrated representation. For example, if a listener is to understand an utterance, then at least the following processes need to be successfully completed: (a) recognition of the signal as speech (as opposed to some other kind of noise), (b) segmentation of the signal into constituent parts, (c) access to the mental lexicon based on

the products of the segmentation process, (d) selection of the appropriate word from within a lexicon containing some 30,000 or more entries, (e) construction of the appropriate grammatical structure for the utterance up to and including the word last processed, and (f) ascertaining the semantic relations among the words in the sentence. Each of these processes requires the activation of different kinds of knowledge. For example, segmentation involves phonological knowledge, which is largely separate from, for instance, the knowledge involved in grammatical analysis. But knowledge bases like phonology, word meaning, and grammar do not, on their own, yield a meaningful message. While there is no question that integration of these (and other) sources of information is a prerequisite for understanding, considerable controversy surrounds the details.

Which sources of knowledge actually need to be distinguished? Is the system organized into modules, each operating within a representational subdomain and dealing with a specific subprocess of comprehension? Or are the representational distinctions less marked or even absent? What is the temporal processing nature of comprehension? Does understanding proceed via a fixed temporal sequence, with limited crosstalk between processing stages and representations? Or is comprehension the result of more or less continuous interaction among many sources of linguistic and nonlinguistic knowledge? These questions, which are among the most persistent in language research, are now gaining the attention of cognitive neuroscientists. This is an emerging field, with a short history. Nevertheless, progress has been made, and we present a few specific examples in this chapter.

A cognitive neuroscience approach to language might contribute to language research in several ways. Neurobiological data can, in principle, provide evidence on the representational levels that are postulated by different language models—semantic, syntactic, and so on (see the section on PET/fMRI). Neurobiological data can

COLIN M. BROWN and PETER HAGOORT Neurocognition of Language Processing Research Group, Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands
MARTA KUTAS Department of Cognitive Science, University of California, San Diego, Calif.

reveal the temporal dynamics of comprehension, crucial for investigating the different claims of sequential and interactive processing models (see the sections on the N400 and the P600/SPS). And, by comparing brain activity within and between cognitive domains, neurobiological data can also speak to the domain-specificity of language. It is, for example, a matter of debate whether language utilizes a dedicated working-memory system or a more general system that subserves other cognitive functions as well (see the section on slow brain-potential shifts).

Postlexical syntactic and semantic integration processes

In this chapter we focus specifically on what we refer to as postlexical syntactic and semantic processes. We do not discuss the processes that precede lexical selection (see Norris and Wise, chapter 60, for this subject), but rather concern ourselves with processes that follow word recognition. Once a word has been selected within the mental lexicon, the information associated with this word needs to be integrated into the message-level representation that is the end product of comprehension. If this integration is to be successful, both syntactic and semantic analyses need to be performed.

At the level of syntax, the sentence needs to be parsed into its constituents, and the syntactic dependencies among constituents need to be specified (e.g., What is the subject of the sentence? Which verbs are linked with which nouns?). At the level of semantics, the meaning of an individual word needs to be merged with the representation that is being built up of the overall meaning of the sentence, such that thematic roles like agent, theme, and patient can be ascertained (e.g., Who is doing what to whom?). These syntactic and semantic processes lie at the core of language comprehension. Although words are indispensable bridges to understanding, it is only in the realm of sentences (and beyond in discourses) that they achieve their full potential to convey rich and varied messages.

The field of language research lacks an articulated model of how we achieve (mutual) understanding. This lack is not too surprising when we consider the problems that confront us in devising a theory of meaning for natural languages, let alone the difficulties attendant on combining such a representational theory with a processing model that delineates the comprehension process at the millisecond level. However understandable, the lack of an overall model has meant that the processes involved in meaning integration at the sentential level have received scant experimental attention. The one area in which quite specific models of the relation-

ship between semantic representations and on-line language processing have been proposed is the area of parsing research. Here, a major concern has been to assess the influence of semantic representations on the syntactic analysis of sentences, with a particular focus on the moments at which integration between meaning and structure occurs (cf. Frazier, 1987; Tanenhaus and Trueswell, 1995). Research in this area has concentrated on the on-line resolution of sentential-syntactic ambiguity (e.g., "The woman sees the man with the binoculars." Who is holding the binoculars?). The resolution of this kind of ambiguity speaks to the separability of syntax and semantics, as well as to the issue of sequential or interactive processing. The prevailing models in the literature can be broadly separated into autonomist and interactive accounts.

In *autonomous approaches*, a separate syntactic knowledge base is used to build up a representation of the syntactic structure of a sentence. The prototypical example of this approach is embodied in the Garden-Path model (Frazier, 1987), which postulates that an intermediate level of syntactic representation is a necessary and obligatory step during sentence processing. This model stipulates that nonsyntactic sources of information (e.g., message-level semantics) cannot affect the parser's initial syntactic analysis (see also Frazier and Clifton, 1996; Friederici and Mecklinger, 1996). Such sources come into play only after a first parse has been delivered. When confronted with a sentential-syntactic ambiguity, the Garden-Path model posits principles of economy, on the basis of which the syntactically least complex analysis of the alternative structures is chosen at the moment the ambiguity arises. If the chosen analysis subsequently leads to interpretive problems, this triggers a syntactic reanalysis.

In the most radical *interactionist approach*, there are no intermediate syntactic representations. Instead, undifferentiated representational networks are posited, in which syntactic and semantic information emerge as combined constraints on a single, unified representation (e.g., Bates et al., 1982; Elman, 1990; McClelland, St. John, and Taraban, 1989). In terms of the processing nature of the system, comprehension is described as a fully interactive process, in which all sources of information influence the ongoing analysis as they become available.

A third class of models sits somewhere in between the autonomous and radical interactionist approaches. In these so-called *constraint-satisfaction models*, lexically represented information (such as the animacy of a noun or the transitivity of a verb) but also statistical information about the frequency of occurrence of a word or of syntactic constructions play a central role (cf. MacDonald, Pearlmutter, and Seidenberg, 1994; Spivey-Knowlton

and Sedivy, 1995). The approach emphasizes the interactive nature of comprehension, but does not exclude the existence of separate representational levels as a matter of principle. Comprehension is seen as a competition among alternatives (e.g., multiple parses), based on both syntactic and nonsyntactic information. In this approach, as in the more radical interactive approach, sentential-syntactic ambiguities are resolved by the immediate interaction of lexical-syntactic and lexical-semantic information, in combination with statistical information about the relative frequency of occurrence of particular syntactic structures, and any available discourse information, without appealing to an initial syntax-based parsing stage or a separate revision stage (cf. Tanenhaus and Trueswell, 1995).

Although we have discussed these different models in the light of sentential-syntactic ambiguity resolution, their architectural and processing assumptions hold for the full domain of sentence and discourse processing. Clearly, the representational and processing assumptions underlying autonomous and (fully) interactive models have very different implications for an account of language comprehension. We will return to these issues after giving an overview of results from the brain-imaging literature on syntactic and semantic processes during sentence processing.

Before discussing the imaging data, a few brief comments on the sensitivity and relevance for language research of different brain-imaging methods are called for. The common goal in cognitive neuroscience is to develop a model in which the cognitive and neural approaches are combined, providing a detailed answer to the very general question of where and when in the brain what happens. Methods like event-related brain potentials (ERPs), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) are not equally revealing or relevant in this respect. In terms of the temporal dynamics of comprehension, only ERPs (and their magnetic counterparts from magnetoencephalography, MEG) can provide the required millisecond resolution (although recent developments in noninvasive optical imaging indicate that near-infrared measurements might approach millisecond resolution; cf. Gratton, Fabiani, and Corballis, 1997). In contrast, the main power of PET and fMRI lies in the localization of brain areas involved in language processing (although recent advances in neuronal source-localization procedures with ERP measurements are making this technique more relevant for localizational issues; cf. Kutas, Federmeier, and Sereno, 1999). Recent analytic developments in PET and fMRI research further indicate that information on effective connectivity in the brain (i.e., the influence that one neuronal system exerts over an-

other) might begin to constrain our models of the language system (cf. Büchel, Frith, and Friston, 1999; Friston, Frith, and Frackowiak, 1993). However, localization as such does not reveal the nature of the activated representations: The hemodynamic response is a quantitative measure that does not of itself deliver information on the nature of the representations involved. The measure is maximally informative when separate brain loci can be linked, via appropriately constraining experimental conditions, with separate representations and processes. A similar situation holds for the ERP method: The polarity and scalp topography of ERP waveforms can, in principle, yield qualitatively different effects for qualitatively different representations and/or processes, but only appropriately operationalized manipulations will make such effects interpretable (cf. Brown and Hagoort, 1999; Osterhout and Holcomb, 1995). In short, whatever the brain-imaging technique being used, the value of the data critically depends on its relation to an articulated cognitive-functional model.

Cognitive neuroscience investigations of postlexical integration

EVENT-RELATED BRAIN POTENTIAL MANIFESTATIONS OF SENTENCE PROCESSING Space limitations rule out an introduction on the neurophysiology and signal-analysis techniques of event-related brain potentials (see Picton, Lins, and Scherg, 1995, for a recent review). It is, however, important to bear in mind that, owing to the signal-to-noise ratio of the EEG signal, one cannot obtain a reliable ERP waveform in a standard language experiment without averaging over at least 20–30 different tokens within an experimental condition. Thus, when we speak of the ERP elicited by a particular word in a particular condition, we mean the electrophysiological activity averaged over different tokens of the same type.

Within the realm of sentence processing, four different ERP profiles have been related to aspects of syntactic and semantic processing: (1) A transient negativity over left-anterior electrode sites (labeled the left-anterior negativity, LAN) that develops in the period roughly 200–500 ms after word onset. The LAN has been related not only to the activation and processing of syntactic word-category information, but also to more general processes of working memory. (2) A transient bilateral negativity, labeled the N400, that develops between 200 and 600 ms after word onset; the N400 has been related to semantic processing. (3) A transient bilateral positivity that develops in the period between 500 and 700 ms. Various labels the syntactic positive shift (SPS) or the P600, this positivity has been related to syntactic processing. (4) A slow positive shift over the front of the

head, accumulating across the span of a sentence, that has been related to the construction of a representation of the overall meaning of a sentence. Let us discuss each of these ERP effects in turn.

Left-anterior negativities The LAN is a relative newcomer to the set of language-related ERP effects. Both its exact electrophysiological signature and its functional nature are still under scrutiny. Some researchers have suggested that the LAN is related to early parsing processes, reflecting the assignment of an initial phrase structure based on syntactic word-category information (Friederici, 1995; Friederici, Hahne, and Mecklinger, 1996). Other researchers propose that a LAN is a reflection of working-memory processes during language comprehension, related to the activity of holding a word in memory until it can be assigned its grammatical role in a sentence (Kluender and Kutas, 1993a,b; Kutas and King, 1995). Clearly more research is called for to decide between these quite separate views. One of the pending issues is the uniformity of the LAN. There is variability in both its topography and latency. It is possible, therefore, that more than one LAN exists (some researchers distinguish between an early left-anterior negativity and a later left-anterior negativity; cf. Friederici, 1995), with different functional interpretations.

An example of a left-anterior negativity is given in figure 61.1 (from work by Kluender and Münte, 1999), in which a preferred and a nonpreferred version (at least in standard Northern German dialects) of a so-called wh-movement is contrasted. The particular wh-movement under investigation is the displacement of the direct object of a verb that occurs when a declarative sentence is transformed into a question-sentence—e.g., the transformation of the declarative “The cautious physicist has stored the data on a diskette” into the question-sentence “What has the cautious physicist stored on a diskette?” In the declarative sentence, *the data* is the direct object of its immediately preceding verb. In the question-sentence, *the data* has been replaced by the interrogative pronoun *what*, which, moreover, has been moved to the beginning of the sentence. (This is, therefore, an instance of wh-movement, where *wh* is a shorthand notation for the category of interrogative words, such as *what*, *who*, *which*, etc.) Although *the data* no longer appears in the question-sentence, syntactically speaking, the wh-element *what* is extracted from the direct-object position to sentence-initial position, leaving a trace after *stored* (i.e., “What_i has the cautious physicist stored _____i on a diskette?”). This trace is presumed to co-index the empty syntactic position after *stored* in the question-sentence with the pronoun *what* in sentence-initial position.

The comparison in the figure concerns a preferred and a nonpreferred wh-movement in standard Northern German dialect. The nonpreferred movement elicited a focal left-anterior negativity. This result is particularly interesting because it adds to the set of syntactic phenomena that have been associated with left-anterior negativities. The effect that Kluender and Münte obtained is incompatible with an interpretation in terms of a violation of expected syntactic word-category information: The word that elicits the LAN effect does not violate category constraints. One hypothesis is that the effect is reflecting a disruption in the primary parsing process of working out the co-index relationship that is indicated by the first part of the wh-question, with a concomitant sudden increase in working-memory load.

The N400 component Of all the ERP effects that have been related to language, the N400 is the most firmly established component (Kutas and Hillyard, 1980). This negative-polarity potential with a maximal amplitude at approximately 400 ms after stimulation onset is, as a rule, elicited by any meaningful word (especially nouns, verbs, and adjectives, sometimes referred to as open-class words) presented either in isolation, in word-word contexts (e.g., priming paradigms) or in sentences. The effect starts some 200–250 ms after word onset and can last for some 200–300 ms; it is widely distributed over the scalp, with a tendency toward greater amplitudes over more central and posterior electrode sites. Although originally demonstrated for sentence-final words that violate the semantic constraints of sentences (e.g., “The woman spread her toast with hypotheses”), more than 15 years of research has demonstrated that this component is not a simple incongruity detector; rather, it is a sensitive manifestation of semantic processing during on-line comprehension (for reviews see Kutas and Van Petten, 1994; Osterhout and Holcomb, 1995). An example of this sensitivity is given in figure 61.2, which shows the ERP waveform elicited by two visually presented words that differ in the extent of their semantic fit with preceding discourse. In this experiment subjects read sentences for comprehension, without having to perform any extraneous task. (This is an advantage of the ERP method compared to the reaction-time method, where one must always consider additional processes, such as lexical decision, due to the external task.) Subjects were presented with a short discourse followed by one of two sentences containing a critical word. The critical word was entirely acceptable within the restricted context of the final sentence itself, but in one case the critical word did not match the message-level meaning set up by the preceding discourse. For example:

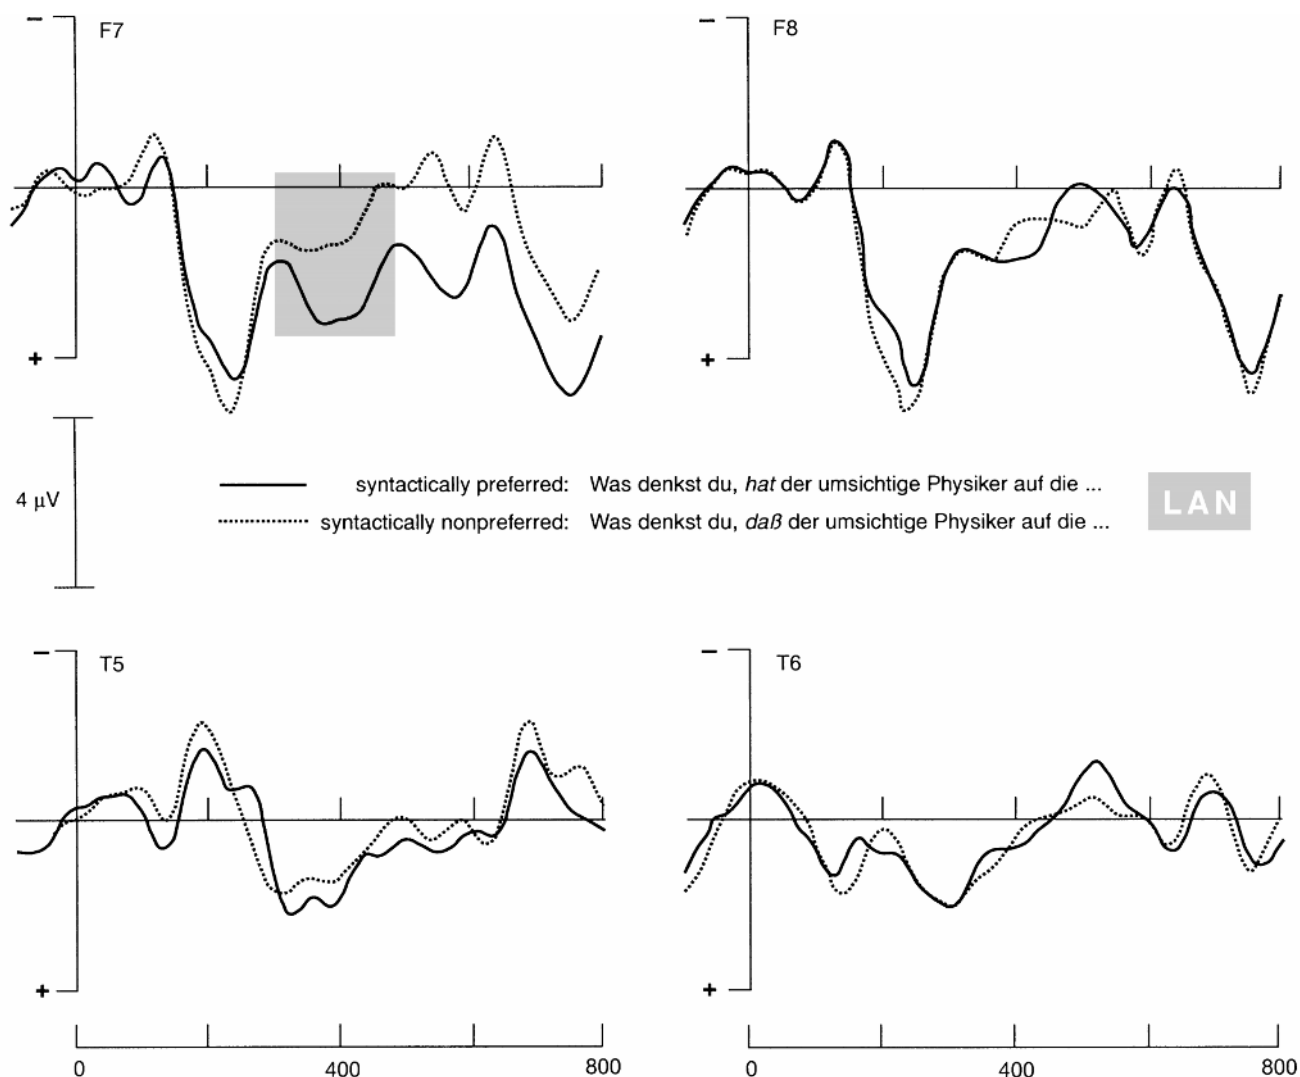

FIGURE 61.1 Grammatical movement effect. The solid line represents the average ERP waveform for a grammatically preferred continuation. The dotted line represents the average waveform for the grammatically nonpreferred continuation. Preferred sentence (critical word in *italics*, to which the ERP waveform is time-locked): “Was denkst du, *hat* der umsichtige Physiker auf die Diskette gespeichert?” (literally translated: “What think you, has the cautious physicist on the disk stored?”). Nonpreferred sentence: “Was denkst du, *daß* der umsichtige Physiker auf die Diskette gespeichert hat?” (literal

translation: “What think you, that the cautious physicist on the disk stored has?”). In wh-question sentences in Northern German dialects, the complementizer *daß* at the beginning of an embedded clause is less preferred in combination with the movement of direct objects to sentence-initial position. Four electrode positions are shown, two over left- and right-anterior sites, and two over left and right temporal sites. Negative polarity is plotted upward, in microvolts. (Data from Kluender and Münte, 1999.)

Discourse: “As agreed upon, Jane was to wake her sister and her brother at 5 o’clock. But the sister had already washed herself, and the brother had even got dressed.”

Normal continuation: “Jane told the brother that he was exceptionally *quick* today.”

Anomalous continuation: “Jane told the brother that he was exceptionally *slow* today.”

As figure 61.2 shows, both words (*quick*, *slow*) elicit the N400 component, with an onset at about 200–250 ms. This underscores the general observation that each

meaningful word in a sentence elicits an N400. The difference in the match between the meaning of the critical word and the meaning of the discourse emerges as a difference in the overall amplitude of the N400, with the mismatching word eliciting the largest amplitude. The amplitude difference is referred to as the N400 effect. Clearly, this N400 effect can emanate only from an attempt to integrate the meaning of the critical word within the discourse. This testifies both to the semantic sensitivity of the N400 and to the integrational processes

FIGURE 61.2 Discourse-semantic N400 effect. The solid line represents the average ERP waveform for the normal continuation of the discourse, and the dotted line for the anomalous continuation. In the figure, the potential elicited by the critical word starts at 600 ms, and is preceded and followed by the po-

tentials elicited by the word before and after the critical word. Three electrode positions are shown: one over the posterior midline of the scalp (Pz), and one each on left and right lateral temporal-posterior sites (LTP and RTP). (Data from Van Berkum, Hagoort, and Brown, 1999.)

that are manifest in modulations of N400 amplitude (see also St. George, Mannes, and Hoffman, 1994, 1997). Note, moreover, that the onset latency of the effect reveals that these high-level processes are already operative within some 200 ms of the word's occurrence. The very early moment at which high-level discourse information is modulating the comprehension process is less readily compatible with strictly sequential models, in which lower-level analyses have to be completed before higher levels of information can affect comprehension.

For present purposes a synopsis of five main findings on the N400 suffices to exemplify its relevance for the study of postlexical processes: (1) The amplitude of the N400 is inversely related to the cloze probability of a word in sentence context. The better the semantic fit between a word and its context, the smaller the amplitude of the N400. (2) This inverse relationship holds for single-word, sentence, and discourse contexts. (3) The amplitude of the N400 varies with word position. Open-class words at the beginning of a sentence elicit larger negativities than open-class words in later positions. This most likely reflects the incremental impact of semantic constraints throughout the sentence. (4) The elicitation of the N400 is independent of input modality—naturally produced connected speech, sign language, or slow and fast visual stimulation. (5) Grammatical processes typically do not directly elicit larger N400s, although difficulty in grammatical processing subsequently gives rise to N400 activity in some cases.

On the basis of these findings it is by now widely accepted that, within the domain of language comprehension, the elicitation of the N400 and the modulations in N400 amplitude are indicative of the involvement of semantic representations and of differential semantic processing during on-line language comprehension. Note

that the claim is not that the N400 is a language-specific component (i.e., modulated solely by language-related factors); rather, in the context of language processing, N400 amplitude variation is linked to lexical and message-level semantic information. In terms of the functional interpretation of the N400 effect, it has been suggested that the effect is a reflection of lexical integration processes. After a word has been activated in the mental lexicon, its meaning has to be integrated into a message-level conceptual representation of the context within it occurs. The hypothesis is that it is this meaning-integration process that is manifest in the N400 effect. The more difficult the integration process is, the larger the amplitude of the N400 (Brown and Hagoort, 1993, 1999; Kutas and King, 1995; Osterhout and Holcomb, 1992).

The P600, or syntactic positive shift (SPS) The P600/SPS, which is of more recent origin, was first reported as a response to syntactic violations in sentences (Hagoort, Brown, and Groothusen, 1993; Osterhout and Holcomb, 1992). For example, in the sentence “The spoilt child throw the toy on the ground,” the grammatical number marking on the verb *throw* does not agree with the fact that the grammatical subject of the sentence (i.e., the *spoilt child*) is singular. This kind of agreement error elicits a positive shift that starts at approximately 500 ms after the violating word (in this case *throw*) has been presented. The shift can last for more than 300 ms, and is widely distributed over the scalp, with posterior maxima. Since its discovery in the early nineties, the P600/SPS has been observed in a wide variety of syntactic phenomena (see Osterhout, McLaughlin, and Bersick, 1997, for a recent overview). In the realm of violations, it has been shown that the P600/SPS is elicited by violations of

(a) constraints on the movement of sentence constituents (e.g., “What was a proof *of* criticized by the scientist?”), (b) phrase structure rules (e.g., “The man was upset by the emotional rather *response* of his employer”), (c) verb subcategorization (e.g., “The broker persuaded *to* sell the stock”), (d) subject–verb number agreement (as in the above example), (e) reflexive-antecedent gender agreement (e.g., “The man congratulated *herself* on the promotion”), and (f) reflexive-antecedent number agreement (e.g., “The guests helped *himself* to the food”).

It should be noted that these violations involve very different aspects of grammar. The fact that in each instance a P600/SPS is elicited points toward the syntactic sensitivity of the component. At the same time the heterogeneity of syntactic phenomena associated with the P600/SPS raises questions about exactly what the component is reflecting about the language process. We will return to this issue after presenting further evidence on the sensitivity of the P600/SPS.

The P600/SPS is not restricted to the visual modality, but is also observed for naturally produced connected speech (Friederici, Pfeifer, and Hahne, 1993; Hagoort and Brown, in press; Osterhout and Holcomb, 1993). Furthermore, it has been demonstrated that the P600/SPS is not a mere violation detector. In fact, it can be used to investigate quite subtle aspects of parsing, such as are involved in the resolution of sentential-syntactic ambiguity. For example, in the written sentence “The sheriff saw the cowboy and the Indian spotted the horse in the canyon,” the sentence is syntactically ambiguous until the verb *spotted*. The ambiguity is between a conjoined noun-phrase reading of *the cowboy and the Indian*, and a reading in which *the Indian* is the subject of a second clause, thereby signaling a sentence conjunction. At the verb *spotted* this ambiguity is resolved in favor of the second-clause reading. It has been suggested in the parsing literature that the conjoined noun-phrase analysis results in a less complex syntactic structure than the sentence-conjunction analysis. Furthermore, as we noted above, it has been claimed that the parser operates economically, such that less complex syntactic analyses are preferred over more complex ones. This would imply that during the reading of the ambiguous example sentence, subjects would experience difficulty in parsing the sentence at the verb *spotted*, despite the fact that in terms of its meaning and in terms of the grammatical constraints of the language, the sentence is perfectly in order. This difficulty should become apparent in a comparison with the same sequence of words in which the ambiguity does not arise, and in which the sentence-conjunction reading is the only option, due to the inclusion of an appropriately placed comma: “The sheriff saw the cowboy, and the Indian spotted the

horse in the canyon.” Note that this particular disambiguation obviously only holds for the visual modality.

When we compare the waveform elicited by the critical written verb *spotted* in the ambiguous sentence to that elicited by the same verb in the control sentence, a P600/SPS is seen in the ambiguous sentence. This is shown in figure 61.3, which depicts the ERP waveform, over four representative electrode sites, for the verb *spotted* in the ambiguous and nonambiguous sentence, preceded and followed by one word. This finding demonstrates that the P600/SPS does not depend on grammatical violations for its elicitation. The component can reflect on-line sentence-processing operations related to the resolution of sentential-syntactic ambiguity. Interestingly, the more frontal scalp distribution of the P600/SPS to sentential-syntactic ambiguity resolution differs from the predominantly posterior distribution elicited by syntactic violations. It might be the case, therefore, that there is more than one positive shift under the general heading of P600/SPS (cf. Brown and Hagoort, 1998; Hagoort and Brown, in press).

Given the sensitivity of the P600/SPS to processes related to the resolution of syntactic ambiguity, it is a good tool with which to investigate the impact of lexical-semantic and higher-order (e.g., discourse) meaning representations on parsing. The impact of semantic information during sentence processing is one of the issues that we raised earlier on the processing nature of the parser. Namely, can nonsyntactic knowledge immediately contribute to sentential-syntactic analysis, or is a first-pass structural analysis performed on the basis of only syntactic knowledge? So, in the written sentence “The helmsman repairs the mainsail and the skipper varnishes the mast after the storm,” the same syntactic ambiguity is present as in the cowboy-and-Indian example. But since the meaning of the verb *repair* is compatible only with inanimate objects, a noun-phrase conjunction of *the mainsail and the skipper* can be excluded on semantic grounds (i.e., the helmsman cannot repair the skipper). Nevertheless, parsing models claiming that the first-pass structural assignment is based solely on syntactic information maintain that the conjoined noun-phrase analysis will be initially considered, and preferred over a sentence-conjunction analysis. This claim has been assessed by investigating the ERP waveform to the verb *repair* in the ambiguous sentence and a nonambiguous control (again realized by appropriately inserting a comma, in this case after *the mainsail*). The results were clear: No difference was seen between the unpunctuated ambiguous and the punctuated nonambiguous sentences (cf. Hagoort, Brown, Vonk, and Hoeks, 1999). This indicates that the semantic information carried by the verb *was* immediately used to

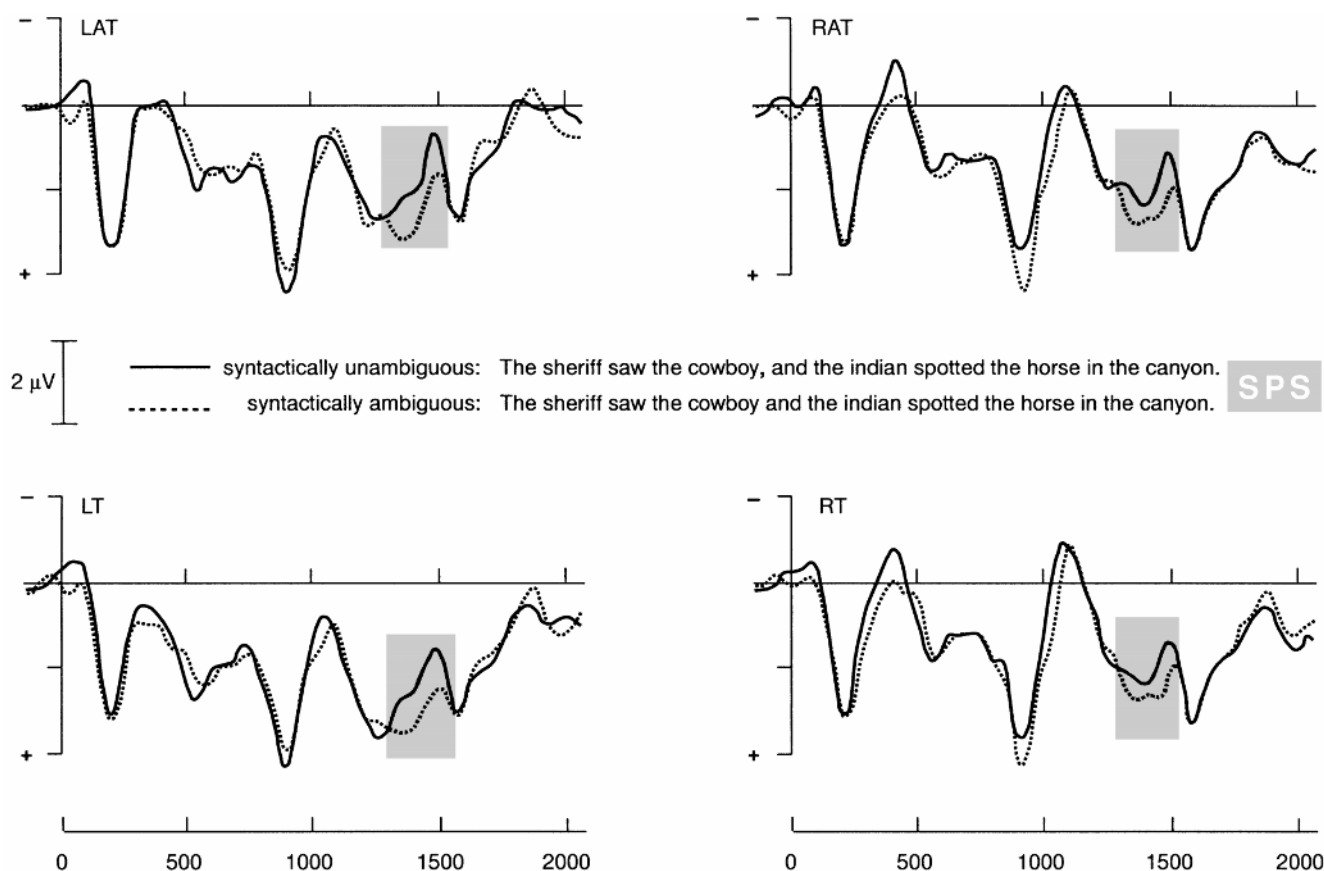

FIGURE 61.3 Sentential-syntactic ambiguity effect. The dotted line represents the average ERP waveform for initially syntactically ambiguous sentences. At the point of disambiguation (at 686 ms) the sentence continued with a grammatically correct but nonpreferred reading. The solid line represents the control condition, in which unambiguous versions of the same nonpreferred structures were presented. In the figure, the critical

word is preceded and followed by one word. The region within which the P600/SPS developed is shaded. Four electrode positions are shown, two over left- and right-anterior temporal sites, and two over left and right temporal sites. (From Brown and Hagoort, 1999. © 1999 Cambridge University Press.)

constrain the ongoing analysis, and thus argues against models that propose an autonomous first-pass structural analysis.

The functional interpretation of the P600/SPS has not yet been fully clarified. Some researchers claim that the late positivity is a member of the P300 family—namely, the so-called P3b component (Coulson, King, and Kutas, 1998; Gunter, Stowe, and Mulder, 1997; but see Osterhout et al., 1996). Other researchers have suggested that the P600/SPS is a reflection of specifically grammatical processing, related to (re)analysis processes that occur whenever the parser is confronted with a failed or nonpreferred syntactic analysis (Friederici and Mecklinger, 1996; Hagoort, Brown, and Groothusen, 1993; Osterhout, 1994; Münte, Matzke, and Johannes, 1997). Note that this position does not necessarily entail any commitment to the language specificity of the component. Rather, the claim advanced by Hagoort, Brown, and Groothusen (1993) and Osterhout (1994) is

that, within the domain of sentence processing, the P600/SPS is a manifestation of processes that can be directly linked to the grammatical properties of language (cf. Osterhout et al., 1996; Osterhout and Hagoort, 1999).

The issue of the functional characterization of the P600/SPS clearly stands to benefit from other areas of brain-imaging research. In particular, localizational techniques such as PET and fMRI could provide crucial information on the commonalities and divergences in the neural circuitry underlying the P600/SPS and the P300.

Despite our still incomplete understanding of the functional nature of the P600/SPS, one important fact already stands out—namely, this component is electrophysiologically distinct from the N400, implying at least a partial separation in the neural tissue that underlies the two components. These electrophysiological findings are therefore directly relevant for the question

Good comprehenders

FIGURE 61.4 Differential comprehension skill effect. Average ERP waveforms recorded at one left-frontal electrode site for object-relative (dotted line) and subject-relative (solid line) sentences, for a group of 12 good and 12 poor comprehenders.

Waveforms are aligned on the first word of each sentence type. The shaded regions indicate areas of statistically significant difference between the two sentence types. (From King and Kutas, 1995. ©1995 MIT Press.)

of the possible separation in the brain of syntactic and semantic knowledge. Sentence-processing models that conflate the processing and/or representational distinctions between syntax and semantics (e.g., McClelland, St. John, and Taraban, 1989) cannot account for these findings.

Slow shifts Language processing beyond the level of the individual word is revealed in ERPs averaged across clauses and sentences (see Kutas and King, 1995). These slow potentials show systematic variation in a variety of sentence types, none of which has to contain any violation. Kutas and King have identified several such slow potentials with different distributions over the left and right side of the head. Of particular relevance is their finding of an ultraslow frontal positivity which has been hypothesized to reflect the linking of

information in working and long-term memory during the creation of a message-level representation of a sentence.

An example of such a slow frontal-positivity from the work of King and Kutas (1995) is shown in figure 61.4. This effect was elicited by the relative processing difficulty of so-called object-relative sentences, compared to subject-relative sentences. In an object-relative sentence, e.g., “The reporter who the senator harshly attacked admitted the error,” the subject of the main clause (*The reporter*) is the object of the relative-clause verb (*attacked*). Such sentences have consistently been shown to be much harder to process than subject-relative sentences, where the subject of the main clause is also the subject of the relative clause (e.g., “The reporter who harshly attacked the senator admitted the error”). This processing difficulty is attributed to the greater working-memory

demands of object-relative sentences, where information has to be maintained in memory over longer stretches of time than for subject-relative sentences.

The figure shows separate pairs of waveforms for two groups of subjects—those with high language comprehension scores and those with low scores. This separation in two groups of subjects is informative because differences in comprehension performance have been linked to differences in working-memory capacity (e.g., King and Just, 1991). Two aspects are particularly noteworthy in these data. First, the waveforms for the object-relative sentences diverge from the slow-frontal positive shift for the subject-relative sentences at the first possible moment of working-memory load difference, i.e., when the second noun-phrase (*the senator*) had to be added to working memory. Second, there are substantial processing differences as a function of comprehension skill and hence, by hypothesis, of working-memory capacity. The slow positivity is present only in the good comprehenders, for whom the increased memory demands of the object-relative sentences emerge as a negative-going deflection from the slow positivity that is characteristic of the subject-relative sentences. In contrast, the poor comprehenders show basically the same ERP profile for the two types of sentences, both being as negative as the waveform elicited by the object-relative sentences in the good comprehenders. It would seem that the poor comprehenders are already maximally taxed by having to cope with any kind of embedded clause.

This finding of differential effects for readers with differing degrees of comprehension skills bears on the question of whether language uses a dedicated working-memory system or draws upon a general system shared by other cognitive functions (Caplan and Waters, in press). A systematic investigation of the (non)linguistic variables that modulate the slow-potential shift will be of direct relevance for this issue. More generally, the finding of long-lasting potentials linked to sentence processing opens the way for investigating the more sustained and incremental effects that wax and wane over the course of an entire sentence.

Summary We have discussed several qualitatively distinct ERP components that can be reliably linked to distinct aspects of language comprehension. On the basis of their different electrophysiological profiles, we can conclude that nonidentical brain systems underlie the various aspects of linguistic processing that are manifest in these different components. This provides a neurobiological constraint for models of language comprehension—models that will need to account for these different patterns of ERP effects.

An important working hypothesis concerns how the basic distinction of meaning and structure in language is

linked to the N400 and the P600/SPS. Research that has used these components to address the basic processing nature of parsing has yielded evidence that is incompatible with strict autonomous characterizations of sentence processing. Furthermore, slow potential shifts that develop over entire clauses and sentences have been linked to integrational processes at the message level, and have demonstrated considerable effects of between-subject working memory differences.

At the temporal level, the millisecond resolution of the electrophysiological signal provides a dynamic picture of the ongoing comprehension process. Different language-related ERP effects are observed to arise at different moments and to persist for differing stretches of time. Within some 200 ms after stimulation, processes related to lexical meaning and integration emerge in the ERP waveform. Some researchers argue that syntactic processes can be seen preceding and partly overlapping with this early onset (cf. LAN effects). Processes related to modifying the ongoing syntactic analysis can be seen at some 500 ms in the ERP waveform. Various co-occurrences of LAN, N400, and P600/SPS effects have been reported, in ways that can be sensibly linked to the on-line comprehension process (e.g., N400 semantic processing effects as a consequence of preceding P600/SPS syntactic processing effects).

LESION AND HEMODYNAMIC DATA ON BRAIN AREAS INVOLVED IN SENTENCE PROCESSING In the previous section we discussed the relevance of ERP data for models of sentence comprehension. The processing of syntactic ambiguities has been a major testing ground for such models. The classical lesion studies and the more recent PET/fMRI studies on sentence comprehension have a slightly different focus. These studies attempt to determine areas that are involved in sentence processing, or to isolate and localize a specific subcomponent of sentence comprehension. This aim is independent of the issue of whether and when different processing components influence each other during sentence comprehension.

Until fairly recently most of the evidence on the neural circuitry of sentence processing came from lesion studies. One of the central issues in this work has been the identification of areas involved in the computation of syntactic structure during language comprehension. The general picture that has emerged from this research is complicated (for a more extensive overview, see Haagoort, Brown, and Osterhout, 1999). Despite the classical association between Broca's area and syntactic functions (e.g., Caramazza and Zurif, 1976; Heilman and Scholes, 1976; Von Stockert and Bader, 1976; Zurif, Caramazza, and Myerson, 1972), detailed lesion analyses have made it doubtful that lesions restricted to this area

result in lasting syntactic deficits (e.g., Mohr et al., 1978). More recent analyses confirm that the left perisylvian cortex is critically involved in both parsing and syntactic encoding. Within this large cortical area it has been difficult to pinpoint a more restricted area that is crucial for syntactic processing. One reason is that lesions in any one part of this cortex can result in syntactic deficits (Caplan, Hildebrandt, and Makris, 1996; Vanier and Caplan, 1990). Moreover, the left anterior-temporal cortex, which has classically not been associated with any particular linguistic function, nonetheless appears to be consistently associated with syntactic deficits (Dronkers et al., 1994). This area is claimed to be involved in morphosyntactic processing, in addition to other areas in the left perisylvian cortex.

The lesion data thus suggest that it is impossible to single out one brain area that is dedicated to syntactic processing. There are at least two reasons for this complicated picture. One is that within the perisylvian cortex, individual variation in the neural circuitry for higher-order language functions might be substantially larger than for functions subserved by the primary sensorimotor cortices (cf. Bavelier et al., 1997; Ojemann, 1991). In addition, the wide variety of “syntactic” manipulations across studies makes it difficult to pinpoint the causal factors underlying the reported variation in brain areas. It is important to keep in mind that the areas involved in parsing (i.e., comprehension) are not necessarily the same as those involved in grammatical encoding (i.e., production), and that processing of word-category information or morphosyntactic features is different from establishing the syntactic dependencies among constituents. While all of these involve syntactic processing at some level, they clearly refer to very different aspects of syntactic processing. Comparing results across studies therefore requires an appreciation of the different syntactic manipulations employed.

Hemodynamic studies So far, PET and fMRI studies on language comprehension have largely focused on single word processing. Very few studies investigated integration processes at the sentence level or beyond (Bavelier et al., 1997; Caplan, Alpert, and Waters, 1998; Indefrey et al., 1996; Mazoyer et al., 1993; Nichelli et al., 1995; Stowe et al., 1994; Stromswold et al., 1996). In all but one of these (Mazoyer et al., 1993), the sentences were presented visually.

Two studies tried to isolate activations related to sentence-level processes from lower-level verbal processing, such as the reading of consonant strings (Bavelier et al., 1997) and single word comprehension (Mazoyer et al., 1993). The very nature of the comparisons in these studies makes it difficult to distinguish between sentence-

level activations related to prosody, syntax, and sentence-level semantics.

The remaining brain-imaging studies on sentence processing were aimed at isolating the syntactic processing component (Caplan, Alpert, and Waters 1998; Indefrey et al., 1996; Just et al., 1996; Stowe et al., 1994; Stromswold et al., 1996). Although these different studies show non-identical patterns of activation, all five report activation in the left inferior-frontal gyrus, including Broca’s area.

Four studies manipulated the syntactic complexity of the sentence materials (Caplan, Alpert, and Waters, 1998; Just et al., 1996; Stowe et al., 1994; Stromswold et al., 1996). For instance, Stromswold et al. (1996) compared sentences that were similar in terms of their propositional content, but differed in syntactic complexity. In one condition sentences with center-embedded structures were presented (e.g., “The juice that the child spilled stained the rug”). The other condition consisted of sentences with right-branching structures (e.g., “The child spilled the juice that stained the rug”). The former structures are notoriously harder to process than the latter. A direct comparison between the structurally complex (center-embedded) and the less complex sentences (right-branching) resulted in activation of Broca’s area, particularly in the pars opercularis.

Caplan, Alpert, and Waters (1998) performed a partial replication of this study. They also observed increased activation in Broca’s area for the center-embedded sentences. However, although the activation was in the pars opercularis, the blood flow increase was more dorsal and more anterior than in the previous study. Factors related to subject variation between studies may account for this regional activation difference within Broca’s area.

In contrast to the other studies on syntactic processing (Caplan, Alpert, and Waters, 1998; Just et al., 1996; Stowe et al., 1996; Stromswold et al., 1996), the critical comparisons in the Indefrey study were not between conditions that differed in syntactic complexity, but rather those that did and did not require syntactic computations. Subjects were asked to read sentences consisting of pseudowords and function words in German [e.g., “(Der Fauper) (der) (die Lüspeln) (febbt) (tecken) (das Baktor)”. Some of the sentences contained a syntactic error (e.g., *tecken*, a number agreement error with respect to the singular subject *Fauper*). In one condition, subjects were asked to detect this error (parsing) and to produce the sentence in its correct syntactic form (“Der Fauper, der die Lüspeln febbt, teckt das Baktor”). The latter task requires grammatical encoding in addition to parsing. In another condition, subjects were only asked to judge the grammaticality of the input string as they read it out. In a third condition, they were asked to make phonological acceptability judgments for the same pseudowords and

function strings, presented without syntactic structure and with an occasional element that violated the phonotactic constraints of German. The experimental conditions were contrasted with a control condition in which subjects were asked to read out unstructured strings of the same pseudowords and function words used in the other conditions. All three syntactic conditions (including the syntactic error detection) were associated with activation of the inferior frontal sulcus between dorsal Broca's area and adjacent parts of the middle frontal gyrus. Both acceptability judgment tasks (syntactic and phonological) showed activation in bilateral anterior inferior frontal areas, as well as in the right hemisphere homologue of Broca's area. These results suggest that the right hemisphere activation that has also been found by others (Just et al., 1996; Nichelli et al., 1995) might reflect error detection. The syntactic processing component that is common across studies seems to be subserved by the left frontal areas.

The first fMRI study at 4 tesla on sentence processing was performed by Bavelier and colleagues (1997). They compared activations due to sentence reading with the activations induced by consonant strings presented like the sentences. Although the design does not allow the isolation of different sentence-level components (e.g., phonological, syntactic, and semantic processing), it nevertheless contains a number of relevant results. Overall, activations were distributed throughout the left perisylvian cortex, including the classical language areas (Broca's area, Wernicke's area, angular gyrus, and supramarginal gyrus). Other parts of the perisylvian cortex were also activated, such as left prefrontal areas and the left anterior-temporal lobe. At the individual subject level, these activations were in several small and distributed patches of cortex. In other visual but nonlanguage tasks, local activations were much less patchy, i.e., containing more contiguous activated voxels than the activations during visual sentence reading. Moreover, the precise pattern of activations varied substantially across individuals. For instance, the activations in Broca's area varied significantly in the precise localization with respect to an individual's main sulci.

If this patchy pattern of activations and the substantial differences across subjects during sentence reading reflect a basic difference between the neural organization of linguistic integration processes and the neural organization of sensory processing, this might in part explain the inconsistency of the lesion and brain-imaging data on sentence-level processing.

Conclusion The data indicate that syntactic processing is based on the concerted action of a number of different areas, each with its own relative specialization. These rela-

tive specializations may include memory requirements for establishing long-distance structural relations, the retrieval of lexical-syntactic information (word classes, such as nouns and verbs; grammatical gender; argument structure; etc.), the use of implicit knowledge of the structural constraints in a particular language to group words into well-formed utterances, and so on. All these operations are important ingredients of syntactic processing. At the same time, they are quite distinct and hence unlikely to be the province of one and the same brain area. The same conclusions apply, *mutatis mutandis*, to semantic integration processes.

In light of the available evidence, it can be argued that sets of areas in the left perisylvian cortex, each having its own relative specialization, contribute to syntactic processing and to important aspects of higher-order semantic processing. Exactly what these specializations are needs to be determined in studies that successfully isolate the relevant syntactic and semantic variables, as specified in articulated cognitive models of listening and reading. In addition, there appears to be restricted but nonetheless salient individual variation in the organization of the language processing networks in the brain, which adds to the complexity of determining the neural architecture of sentence processing (cf. Bavelier et al., 1997).

Broca's area has been found to be especially sensitive to the processing load involved in syntactic processing. It thus might be a crucial area for keeping the output of structure-building operations in a temporary buffer (working memory). The left temporal cortex, including anterior portions of the superior-temporal gyrus is presumably involved in morphosyntactic processing (Dronkers et al., 1994; Mazoyer et al., 1993). The retrieval of lexical-syntactic information, such as word class, supposedly involves the left frontal and left temporal regions (Damasio and Tranel, 1993; Hillis and Caramazza, 1995).

Although lesion and PET/fMRI studies on sentence comprehension have not yet reached the sophistication of bearing results with clear implications for our functional models of parsing and other sentence-level integration processes, they have begun to demarcate the outlines of the neural circuitry involved. Moreover, these studies have raised a number of important issues that have to be dealt with in future studies on the cognitive neuroscience of language. Prime among them is the issue of individual variation.

Cognitive neuroscience research on language comprehension: The next millennium

The ERP work offers us a rich collection of potentials that can be fruitfully related to language comprehension,

providing important constraints on the architecture and mechanisms of the language system. The PET and fMRI research on sentence processing has complemented the lesion work, further delimiting language-related areas in the brain. At the very least, we have a solid basis on which to continue building a cognitive neuroscience research program on language understanding. However, various challenges still lie ahead, two of which we briefly mention here.

First, an appreciation of the differences between the various brain-imaging methods has led to the view that cognitive neuroscience research must bring together the more temporally and spatially sensitive research tools. In fact, it is becoming something of a dogma that ERP/MEG, PET, and fMRI measurements should be combined, preferably in the same experiment. However, a note of caution is called for here: We have, as yet, very little understanding of how the electrophysiological and the hemodynamic signals are related. Without such knowledge, it is difficult to ascertain in what way a particular component of the ERP/MEG signal relates to a hemodynamic response in a specific area of the brain and vice versa. Therefore, any response to the call for a spatiotemporal integrative approach is, at present, more a promise for the future than an actual, substantive research program. For the moment, cognitive neuroscience research on language mirrors the standard methodological division in the brain-imaging field, with separate experiments with ERP and/or MEG methodology, and others with PET or fMRI. Much basic research is needed before it will be clear whether a meaningful (as opposed to a mere technical) marriage of electromagnetic and hemodynamic approaches is possible (see for further discussion Rugg, 1999).

A second issue concerns the PET and fMRI work on sentence processing. Most PET and fMRI language researchers have, perhaps understandably, steered clear of the complexities of integrational processes during comprehension; however, the field needs a concerted effort in this area. Language understanding entails much more than word recognition, and we must expand our knowledge of the neural architecture to include the circuitry involved in postlexical integration. A particular challenge for PET and fMRI work will be to implement research that does justice to the elegance and richness of human language.

ACKNOWLEDGMENTS We thank Robert Kluender, Pim Lev-elt, Jacques Mehler, Tom Münte, and Richard Wise for helpful comments, and Inge Doehring for graphical assistance. 62 Acquisition of Languages: Infant and Adult Data

JACQUES MEHLER AND ANNE CHRISTOPHE

ABSTRACT This chapter advocates a multidimensional approach to the issues raised by language acquisition. We bring to bear evidence from several sources—experimental investigations of infants, studies of bilingual infants and adults, and data from functional brain-imaging—to focus on the problem of early language learning. At bottom, we believe that our understanding of development and knowledge attainment requires the joint study of the initial state, the stable state, and the mechanisms that constrain the timetables of learning. And we are persuaded that such an approach must take into account data from many disciplines.

What advantage can a newborn infant draw from listening to speech? Possibly none, as was thought not so long ago (Mehler and Fox, 1985). But now we conjecture that the speech signal furnishes information about the structure of the mother tongue (see Christophe et al., 1997; Gleitman and Wanner, 1982; Mazuka, 1996; Mehler and Christophe, 1995). This position, dubbed the “phonological bootstrapping” hypothesis (Morgan and Demuth, 1996a), reflects an increasing tendency in language acquisition research (Morgan and Demuth, 1996b; Weissenborn and Höhle, 1999)—namely, that language acquisition starts very early and that a purely phonological analysis of the speech signal (a surface analysis) gives information about the grammatical structure of the language.

Phonological bootstrapping rests on the idea that language is a species-specific ability, the product of a “language organ” specific to human brains. Hardly new, this view has been advocated by psychologists, linguists, and neurologists since Gall (1835). Lenneberg (1967) initially provided much evidence for the biological foundations of language, evidence that has been corroborated by other research programs (for review, see Mehler and Dupoux, 1994; Pinker, 1994). Human brains appear to have specific neural structures, part of the species endowment, that mediate the grammatical systems of language. Noam Chomsky (1988) proposed conceiving of the “knowledge of language” that newborns bring to the

task of acquiring a language in terms of principles and parameters—universal principles that are common to all human languages and parameters that elucidate the diversity of natural languages (together, then, principles and parameters constitute Universal Grammar). Parameters are set through experience with the language spoken in the environment (for a different opinion about how species-specific abilities may be innately specified, see Elman et al., 1996).

In this chapter, we first present experimental results with infants to illustrate the phonological bootstrapping approach. We then examine how word forms can be learned. Finally, we discuss studies of the cortical representation of languages in bilingual adults, who, by being bilingual, exhibit the end result of a special (though frequent) language-learning case. The structure of this chapter illustrates an unconventional view of development. Given the task of presenting language acquisition during the first year of life, why do we include studies on the representation of languages in adult bilinguals? We do so in the belief that development is more than the study of change in developing organisms. To devise an adequate theory of how an initial capacity turns into the full-fledged adult capacity, we need a good description of both endpoints. In addition, considering both endpoints together while focusing on the problem of development is a good research strategy, one that has increased our understanding of language acquisition.

Phonological bootstrapping

In our chapter in the first edition of this book, (Mehler and Christophe, 1995), we started from the fact that many babies are exposed to more than one language—languages that must be kept separate in order to avoid confusion. We reviewed a number of studies that illustrate such babies’ ability to discriminate between languages. The picture that emerged was that, from birth onward, babies are able to distinguish their mother tongue from foreign languages (Bahrick and Pickens, 1988; Mehler et al., 1988); moreover, they show a preference for their mother tongue (Moon, Cooper, and Fifer,

1993). Both these facts hold when speech is low-pass-filtered, preserving only prosodic information (Dehaene-Lambertz and Houston, 1998; Mehler et al., 1988). In addition, after reanalyzing our data (from Mehler et al., 1988), we noticed a developmental trend between birth and 2 months of age: Whereas newborns discriminated between two foreign languages, 2-month-olds did not. More recent data confirm this developmental trend. Thus, Nazzi, Bertoncini, and Mehler (1999) showed that French newborns could discriminate filtered sentences in English and Japanese; and Christophe and Morton (1998) showed that, while English 2-month-olds do not react to a change from French to Japanese (using unfiltered sentences), they do discriminate between English and Japanese in the same experimental setting. A possible interpretation of this counterintuitive result is that, while newborns attempt to analyze every speech sample in detail, 2-month-olds have gained enough knowledge of their mother tongue to be able to filter out utterances from a foreign language as irrelevant. As a consequence, they do not react to a change from one foreign language to another. This takes place when the infant is about 2 months old, and thus marks one of the earliest reorganizations of the perceptual responses as a result of exposure to speech.

When Mehler and colleagues (1996) proposed a framework to explain babies' ability to discriminate languages, they began with two facts: first, that babies discriminate languages on the basis of prosodic properties and, second, that vowels are salient features for babies (see Bertoncini et al., 1988; Kuhl et al., 1992). They conjectured that babies construct a grid-like representation containing only vowels. Such a representation would facilitate the discrimination of the language pairs reported. Indeed, the pairs invariably involved *distant* languages. In addition, it predicts that infants should have most difficulty discriminating languages having similar prosodic/rhythmic properties. It is assumed that the vowel grid represents the languages of the world as clusters around discrete positions in the acoustic space.

Nazzi, Bertoncini, and Mehler (1998) began to test some predictions of this framework. First, they showed that French newborns fail to discriminate English and Dutch filtered sentences. English and Dutch share a number of prosodic properties (complex syllables, vowel reduction, similar word stress) and both are "stress-timed"; they should therefore receive similar grid-like representations. The authors also investigated the question of whether languages receiving similar grid representation would be grouped into one single category—a language family or class. To that end, they selected four languages falling into two language classes: Dutch and English (stress-timed), and Spanish and Ital-

ian (syllable-timed). They presented infants with a mixture of filtered sentences from two different languages. When habituated to sentences in Dutch and English, infants responded to a change to sentences in Spanish and Italian, and vice versa. In contrast, when habituated to English and Spanish and tested with Dutch and Italian, infants failed to discriminate. (Note: All the possible interlanguage class combinations were used.) Infants reacted only if a change of language class had taken place (see figure 62.1). These experiments suggest that infants spontaneously classify languages into broad classes or rhythmic-prosodic families, as hypothesized.

So now we know that some languages are more similar than others, even for babies. How can we learn more about the metric underlying perceptual judgments? Two lines of research have allowed us to investigate the perceptual space. One of these exploits adaptation to time-compressed speech (artificially accelerated speech, which is about twice as fast as normal speech). Subjects are asked to listen to and comprehend compressed sentences. Comprehension is initially rather poor; but subjects habituate to compressed speech, and their performance improves after listening to a few sentences (Mehler et al., 1993). Dupoux and Green (1997) observed that adaptation resists speaker change, demonstrating that adaptation takes place at a relatively abstract level. However, Altmann and Young (1993) reported adaptation to compressed speech in sentences composed of nonwords, showing that lexical access is not necessary for adaptation. Similarly, Pallier and colleagues (1998) found that monolingual Spanish subjects listening to Spanish compressed sentences benefit from previous exposure to highly compressed Catalan, a language that they were unable to understand. The same pattern of results was observed when monolingual British subjects were exposed to highly compressed Dutch. Pallier and colleagues (1998) also reported that French-English bilinguals showed no transfer of adaptation from French to English, or vice-versa, again demonstrating that comprehension contributes, at best, very little to adaptation.

These results were interpreted in terms of the phonological (prosodic and rhythmical) similarity of the adapting and the target languages. Phonologically similar languages, such as Catalan and Spanish or English and Dutch, show transfer of adaptation from one member of the pair to the other; however, adaptation to French or English, two phonologically dissimilar languages, does not transfer from one to the other. Sebastian-Gallés, Dupoux, and Costa (in press) extended these findings by adapting Spanish subjects to Spanish, Italian, French, Greek, English, or Japanese sentences. Sebastian-Gallés and colleagues replicated and extended the findings by

FIGURE 62.1 Results of a nonnutritive sucking experiment: Auditory stimulation is presented contingently upon babies' high-amplitude sucks on a blind dummy. After a baseline period without stimulation, babies hear sentences from one category until they reach a predefined habituation criterion. They are then switched to sentences from the second category. The graph displays sucking-rate averages for 32 French newborns for the baseline period, 5 minutes before the change in stimulation, and 4 minutes after the change. The rhythmic group was switched from a mixture of sentences taken from two stress-timed languages (Dutch and English) to a mixture of sentences

from two syllable-timed languages (Spanish and Italian), or vice versa. The nonrhythmic group also changed languages, but in each phase of the experiment there were sentences from one stress-timed and one syllable-timed language (e.g., Spanish and English, then Italian and Dutch). Infants from the rhythmic group reacted significantly more to the change of stimulation than infants from the nonrhythmic group, indicating that only those in the rhythmic group were able to form a category with the habituation sentences and notice a change in category (syllable-timed vs. stress-timed). (Adapted from Nazzi, Bertoncini, and Mehler, 1998.)

Pallier and co-workers; in particular, they observed that Greek, which shares rhythmic properties with Spanish but has little lexical overlap, is very efficient in promoting adaptation to Spanish. These authors concluded that the technique of time-compressed speech can serve as a tool to explore the grouping of languages into classes. Another technique being assessed as a tool to study the metric of natural languages is speech resynthesis—a procedure that makes it possible to selectively preserve some aspects of the original sentences, such as phonemes, phonotactics, rhythm, and intonation (see Ramus and Mehler, 1999). It is too early to relate these early categorizations of languages with the language classifications proposed by comparative linguists and biologists (see Cavalli-Sforza, 1991; Renfrew, 1994).

So far, we have seen that the languages of the world can be organized on a metric; that is, some languages are more distant than others. This metric could be discrete, like the one Miller and Nicely (1955) proposed for

phonemes—a space structured by a finite number of dimensions (e.g., the parameters within the principles-and-parameters theory). Or it could be a continuous space, without structure, with as many dimensions as there are languages. Mehler and colleagues (1996) claimed that the first option should be correct because the metric of languages, the underlying structure, could aid in acquisition. The way a language sounds (i.e., its phonological information) would help infants to discover some properties of their native language and allow them to start the process of acquisition. This is a kind of phonological bootstrapping.

One recent proposal (Nespor, Guasti, and Christophe, 1996) illustrates how phonological information may bootstrap the acquisition of syntax. Languages vary as to the way words are organized in sentences. Either complements follow their heads, as in English or Italian (e.g., *He reads the book*, where *book* is the complement of *reads*), or they precede their heads, as in Turkish or Japanese

(e.g., *KitabI yazdim* [*The-book I-read*]). This structural property possesses a prosodic correlate: In head-initial languages like English, prominence falls at the end of phonological phrases (small prosodic units, e.g., *the big book*), but in head-final languages like Turkish, prominence falls at the beginning of phonological phrases. Therefore, if babies can hear whether prominence falls at the beginning or end of phonological phrases, they can decipher their language's word order. Infants could understand some structural aspects before they learn words (see Mazuka, 1996, for a discussion). They could use their knowledge of the typical order of words in their mother tongue to guide the acquisition of word meanings (e.g., see Gleitman, 1990).

If babies are to use prosodic information to determine the word order of their language, they should first be able to perceive the prosodic correlates of word order. In order to test the plausibility of this hypothesis, Christophe and colleagues (1999) compared two languages that differ on the head-direction parameter, but have otherwise similar prosodic properties: French and Turkish. Both languages have word-final stress, fairly simple syllabic structure through resyllabification, and no vowel reduction. Matched sentences in the two languages were constructed such that they had the same number of syllables, and their word boundaries and phonological phrase boundaries fell in the same places. Only prominence within phonological phrases distinguished these sentences. They were read naturally by native speakers of French and Turkish. And, in order to eliminate phonemic information while preserving prosodic information, the sentences were resynthesized so that all vowels were mapped to schwa and consonants by manner of articulation (stops, fricatives, liquids, etc.). The prosody of the original sentences was copied onto the resynthesized sentences. An initial experiment showed that 2-month-old French babies were able to distinguish between these two sets of sentences (see also Guasti et al., in press). This result suggests that babies are able to perceive the prosodic correlate of word order well before the end of the first year of life (although additional control experiments are needed to rule out alternative explanations). As they stand, the findings support the notion that babies determine the word order of their language before the end of the first year of life—about the time that lexical and syntactic acquisition begins.

This proposal is an example of how purely phonological information (in that case, prosodic information) directly gives information about syntax. Languages differ not only in syntax, but in their phonological properties as well; and babies may learn about these properties of their mother tongue early in life. (The alternative is that children learn the phonology of a language when they

learn its lexicon, after age 1). In fact, recent experiments have shown that the adult speech processing system is shaped by the phonological properties of the native language (e.g., Cutler and Otake, 1994; Otake et al., 1996; see Pallier, Christophe, and Mehler, 1997, for a review). For instance, Dupoux and his colleagues examined Spanish and French adult native speakers' processing of stress information (stress is contrastive in Spanish: *BEbe* and *beBE* are different words, meaning "baby" and "drink," respectively; in French stress is uniformly word-final). They used an ABX paradigm where subjects listened to triplets of pseudowords and had to decide whether the third one was like the first or like the second one (Dupoux et al., 1997). They observed that French native speakers were almost unable to make the correct decision when stress was the relevant factor (e.g., *VAsuma*, *vaSUma*, *VAsuma*, correct answer first item), whereas Spanish speakers found it as straightforward to monitor for stress as to monitor for phonetic content. In addition, Spanish speakers found it very hard to base their decision on phonemes when stress was an irrelevant factor (e.g., *VAsuma*, *faSUma*, *vaSUma*, correct answer first item), whereas French speakers happily ignored the stress information. In another set of experiments, Dupoux and colleagues investigated the perception of consonant clusters and vowel length in French and Japanese speakers (Dupoux et al., in press). In French, consonant clusters are allowed but vowel length is irrelevant, while in Japanese, consonant clusters are not allowed and vowel length is relevant. They observed that Japanese speakers were at chance level in an ABX task when the presence of a consonant cluster was the relevant variable (e.g., *ebzo*, *ebu zo*, *ebu zo*, correct answer second item), whereas they performed very well when they had to base their decision on vowel length (e.g., *ebu zo*, *ebu zo*, *ebu zo*, correct answer first item). In contrast, French speakers showed exactly the reverse pattern of performance (see figure 62.2).

All these results suggest that adult speakers of a language listen to speech through the filter of their own phonology. Presumably, they represent all speech sounds with a sublexical representation that is most adequate for their mother tongue, but inadequate for foreign languages. How and when do babies learn about such phonological aspects of their mother tongue? Although we still lack experimental results on this topic, we conjecture that babies must stabilize the correct sublexical representation for their mother tongue sometime during the first year of life. Thus, when they start acquiring a lexicon toward the end of their first year, they may directly establish lexical representations in a format that is most suitable to their mother tongue. Consistent with this view, evidence is emerging that the representations in adults' auditory in-

FIGURE 62.2 Reaction times (in gray) and error rates (in black) to ABX judgments in French and Japanese subjects on a vowel length contrast and on an epenthesis contrast. (Adapted from Dupoux et al., 1999.)

put lexicon depend on the phonological properties of the native language (Pallier, Sebastian-Gallés, and Colomé, 1999).

Here we have discussed one particular kind of phonological bootstrapping, whereby the way a language sounds gives information as to its abstract structure (such as the head-direction parameter, or the kind of sublexical representation it uses). Phonological information may help bootstrap acquisition in other ways (Morgan and Demuth, 1996a): For instance, prosodic boundary information may help parse a sentence (e.g., Morgan, 1986); prosodic and distributional information may help reveal word boundaries (e.g., Christophe and Dupoux, 1996; Christophe et al., 1997); and phonological information may help to categorize words (see Morgan, Shi, and Allopenna, 1996). This is not to imply that everything about language can be learned through a purely phonological analysis of the speech signal during the first year of life and before anything else has been learned. Of course this is not the case. For instance, although we argued that some syntactic properties may be cued by prosodic correlates (e.g., the head-direction parameter), we

do not claim that prosody contains traces for *all* syntactic properties. But if the child can discover only a few basic syntactic properties from such traces, learning is made easier. The number of possible grammars diminishes by half with each parameter that is set (for binary parameters). As a consequence, the first parameter that is set eliminates the largest number of candidate grammars (see Fodor, 1998; Gibson and Wexler, 1994; Tesar and Smolensky, 1998, for discussions about learnability). In other words, a purely phonological analysis may *bootstrap* the acquisition process but not solve it entirely. Fernald and McRoberts (1996) also discussed the potential help of prosody in bootstrapping syntactic acquisition: They criticized this approach on the grounds that the proportion of syntactic boundaries reliably cued by prosodic cues (pauses, lengthening, etc.) is not high. Some syntactic boundaries are not marked and some cues appear in inadequate positions. If so, children may often think that a syntactic boundary is present when none is and posit erroneous grammars. This argument holds only if one assumes that children use prosodic boundaries to parse every sentence they hear. Infants' brains may instead keep statistical tabs established on the basis of prosody and use such information to learn something about their language. For instance, they may tally the most frequent syllables at prosodic edges, in which case they find the function words and morphemes of their language at the top of the list. In that view, it does not matter very much if prosodic boundaries do not correlate perfectly with syntactic boundaries.

Learning words

Learning the syntax and phonology of their native language is not all babies have to do to acquire a functioning language. They also have to learn the lexicon—an arbitrary collection of word forms and their associated meanings (word forms respect the phonology of the language, but there is no systematic relationship between form and meaning). Experimental work shows that babies start to know the meaning of a few words at about 1 year of age (Oviatt, 1980; Thomas et al., 1981), and this is consistent with parental report. Mehler, Dupoux, and Segui (1990) argued that infants must be able to segment and store word forms in an appropriate language-specific representation before the end of the first year of life in order to be ready for the difficult task of linking word forms to their meaning (Gleitman and Gleitman, 1997). Recent experiments by Peter Jusczyk and colleagues supported this view by showing that babies are able to extract word forms from the speech stream and remember them by about 8 months of age. Jusczyk and Aslin (1995) showed that 7.5-month-olds attended less to new

words than to “familiar” words—i.e., isolated monosyllabic words with which they had been familiarized in the context of whole sentences. This result was later replicated with multisyllabic words, indicating that babies of this age have at least some capacity to extract word-like units from continuous speech (Jusczyk, Houston, and Newsome, in press). These word forms are not forgotten immediately afterwards. When 8-month-olds were repeatedly exposed to recorded stories at home then brought into the lab a week later, they exhibited a listening preference to words that frequently occurred in these stories (Jusczyk and Hohne, 1997).

How do babies extract word forms from the speech stream? This area of research has exploded since our last version of this chapter, and we now have a reasonably good view of what babies might do. Babies may exploit distributional regularities (i.e., segments belonging to a word tend to cohere). Brent and Cartwright (1996) showed that an algorithm exploiting these cues could recover a significant number of words from unsegmented input. In addition, Morgan (1994) demonstrated that 8-month-old babies exploited distributional regularity to package unsegmented strings of syllables (see also Saffran, Aslin, and Newport, 1996). Babies may also exploit the phonotactic regularities of the language, such as the fact that some strings of segments occur only at the beginning or at the end of words. Babies may learn about these regularities by examining utterance boundaries, then use these regularities to find word boundaries (Brent and Cartwright, 1996; Cairns et al., 1997). Interestingly, Friederici and Wessels (1993) showed that at 9 months, babies are already sensitive to the phonotactic regularities of their native language (see also Jusczyk, Cutler, and Redanz, 1993; Jusczyk, Luce, and Charles-Luce, 1994).

Next, babies may rely on their knowledge of the typical word shapes of their language. Anne Cutler and her colleagues extensively explored a well-known example of such a strategy in English. Cutler’s metrical segmentation strategy relies on the fact that English content words predominantly start with a strong syllable (containing a full vowel, as opposed to a weak syllable containing a reduced vowel). Adult English-speaking listeners make use of this regularity when listening to faint speech or when locating words in nonsense syllable strings (e.g., Cutler and Butterfield, 1992; McQueen, Norris, and Cutler, 1994). Importantly, 9-month-old American babies prefer to listen to lists of strong-weak words (bisyllabic words in which the first syllable is strong and the second weak) than to lists of weak-strong words (Jusczyk, Cutler, and Redanz, 1993). In addition, Peter Jusczyk and his colleagues showed, in a recent series of experiments, that babies of about 8 months find it easier to segment

strong-weak (SW) words than weak-strong (WS) words from passages (Jusczyk, Houston, and Newsome, in press).

Finally, babies may rely on prosodic cues to perform an initial segmentation of continuous speech. Prosodic units roughly corresponding to phonological phrases (small units containing one or two content words plus some grammatical words or morphemes) were shown to be available to adult listeners (de Pijper and Sanderman, 1994), and presumably to babies as well (Christophe et al., 1994; Gerken, Jusczyk, and Mandel, 1994; see also Morgan, 1996; Fisher and Tokura, 1996, for evidence that prosodic boundary cues have robust acoustic correlates in infant-directed speech). These prosodic units would not allow babies to isolate every word; however, they would provide a first segmentation of the speech stream and restrict the domain of operation of other strategies (e.g., distributional regularities). In addition, prosodic units possess the interesting property that they derive from syntactic constituents (in a nonisomorphic fashion; see Nespor and Vogel, 1986); as a consequence, function words and morphemes tend to occur at prosodic edges. Therefore, infants may keep track of frequent syllables at prosodic edges, and the most frequent will correspond to the function words and morphemes in their language. Actually, LouAnn Gerken and her colleagues showed that 11-month-old American babies reacted to the replacement of function words by nonwords, indicating that they already knew at least some of the English function words (Gerken, 1996; and Shafer et al., 1998). Once babies have identified the function words of their native language, they may “strip” syllables homophonous to function words from the beginning and end of prosodic units; the remainder can then be treated as one or several content words.

This area of research illustrates particularly well the advantages of studying adults and babies simultaneously. For instance, the fact that English speakers rely on the predominant word pattern of English to perform lexical segmentation was first shown for adult subjects; this result was then extended to babies between 8 and 12 months of age. Reciprocally, the use of prosody to hypothesize word or syntactic boundaries was first advocated to solve the acquisition problem, and is now being fruitfully studied in adults (e.g., Warren et al., 1995).

The bilingual brain

We have argued that the speech signal provides fairly useful hints to isolate some basic properties of one’s maternal language. There is, however, a situation that presents the infant with incompatible evidence; that is, sometimes two languages are systematically presented at the same time in the environment. But this apparently

insurmountable problem is readily solved by every child raised in a multilingual society—no important delay in language acquisition has been reliably documented. We have to provide a model of language acquisition that can account for that.

Bosch and Sebastian-Gallés (1997) have shown that at 4 months bilingual Spanish/Catalan babies already behave differently than do monolingual controls of either language. These investigators showed that monolingual babies orient faster to their mother tongue (Spanish for half of the babies and Catalan for the other half) than to English. In contrast, bilingual babies orient to Spanish or Catalan significantly more slowly than to English. In more recent and still unpublished work, these authors show that the bilingual infants can discriminate between Spanish and Catalan, indicating that confusion cannot be adduced to explain the above results. Needing to keep the languages separate, bilingual infants might be performing more fine-grained analyses of both Spanish and Catalan, and hence need more processing time.

Does the bilingual baby become equally competent in both languages? To answer this question, we have to study adult bilinguals. Pallier, Bosch, and Sebastian-Gallés (1997) studied Spanish/Catalan bilinguals who learned to speak Catalan and Spanish before the age of 4 (although one language was always dominant—the one spoken by both parents). Whereas Spanish has only one /e/ vowel, Catalan has two, an open and a closed /e/. Pallier and colleagues showed that the Spanish-dominant speakers could not correctly perceive the Catalan vocalic contrast, even though they had had massive exposure to that language and spoke it fluently. Had these subjects been exposed to both languages in the crib, would they have learned both vowel systems? Behavioral studies are not yet readily available.

In the remainder of this section, we will review what brain-imaging techniques can tell us about language representation in bilingual adults. Mazoyer and colleagues (1993) explored brain activity in monolingual adults who were listening to stories in their maternal tongue (French) or in an unknown foreign language (Tamil). Listening to French stories activated a large left hemisphere network including parts of the prefrontal cortex and the temporal lobes—a result that is congruent with the standard teachings of neuropsychology.¹ In contrast, the activation for Tamil was restricted to the midtemporal areas in both the left and right hemispheres. Was the left hemisphere of the French subjects activated by French because it was their mother tongue or because French, in contrast to Tamil, was a language they understood? Perani and colleagues (1996) investigated native Italians with moderate-to-good English comprehension. When

Italians were listening to Italian, they exhibited the same pattern of activation as that reported in the Mazoyer study. Italians listening to and understanding English displayed a weak symmetrical right-hemisphere and left-hemisphere activation. Surprisingly, they displayed a similar activation when listening to stories in Japanese, a language they did not understand.² Comparing the cortical activation to English and Japanese ought to have uncovered the cortical areas dedicated to processing the words, syntax, and semantics of English. Figure 62.3 (see color plate 41) illustrates the fact that our expectation was not fulfilled.

How can we explain this failure? It seems unlikely that natural languages should yield comparable activation regardless of comprehension. An alternative account is that the native language yields the same cortical structures in every volunteer while a second language “shows greater inter-individual variability and therefore fails to stand out when averaged across subjects.” Dehaene and colleagues (1997) used fMRI to explore this possible explanation. They examined eight French volunteers who had a fair understanding of English comparable in proficiency to the bilinguals tested by Perani and co-workers. The French volunteers listened to French or English stories and backward speech in alternation. When listening to French, their mother tongue, they all showed more activity in and around the left superior temporal sulcus. But when they listened to English, left and right cortical activation was highly variable among subjects (see figure 62.4; color plate 42). This result may reflect the fact that a second language may be learned in a number of different ways (e.g., through explicit tuition or more naturally), and hence the end result may vary from one individual to the next. To assess this, we need to examine the cortical representation of the second language when it was learned in a natural setting during childhood.

Perani and colleagues (1998) tried to explore these issues by testing two groups of highly proficient bilinguals. The first were Spanish/Catalan bilinguals who had acquired their second language between ages 2 and 4 and appeared to be equally proficient in both of their languages (but see Pallier, Bosch, and Sebastian-Gallés, 1997, who tested the same population of subjects). The second were Italians who had learned English after the age of 10 and had attained excellent performance. The main finding of this PET study was that the cortical representations of the two languages were very similar (for both groups of high-proficiency bilinguals), and significantly different from that in low-proficiency bilinguals. This study suggests that proficiency is more important than age of acquisition as a determinant of cortical representation of the second language, at least in bilinguals

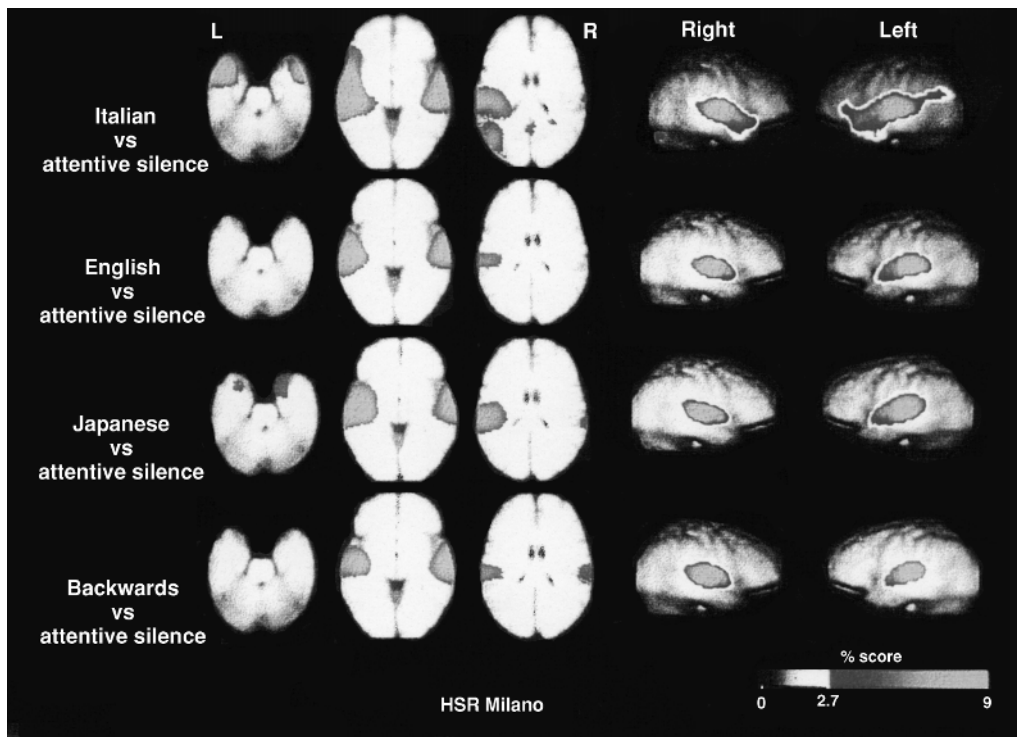

FIGURE 62.3 Patterns of activation in a PET study measuring the activity in Italian speakers' brains while listening to Italian (mother tongue), English (second language), Japanese (unknown language), and backward Japanese (not a possible hu-

man language). There was a significant activation difference between Italian and English. In contrast, English and Japanese did not differ significantly. Japanese differed significantly from backward Japanese. (Adapted from Perani et al., 1996.)

who speak languages that are historically, lexically, and syntactically reasonably close (even though there are phonological differences). All these studies investigated the cortical activation while *listening* to speech. What happens for speech *production*?

Kim and colleagues (1997) investigated a kind of speech production situation: They used fMRI with bilingual volunteers who were silently speaking in either of their languages. They tested bilingual volunteers who mastered their second language either early or late in life (the languages involved in the study were highly varied). They found that the first and second languages have overlapping representation in Broca's area in early learners whereas these representations are segregated in late learners. In contrast, both languages overlap over Wernicke's area regardless of age of acquisition. However, only age of acquisition and not proficiency was controlled; thus it is difficult to evaluate their separate contribution. As Perani and colleagues have indicated, there is a negative correlation between age of acquisition and proficiency (Johnson and Newport, 1989).

How can we harmonize the picture we get from the brain imaging studies with behavioral results? Even with very proficient bilinguals, it has been shown that the languages are not equivalent: People behave as natives in

their dominant language and do not perform perfectly well in the other language. This has been shown for phonetic perception (Pallier, Bosch, and Sebastian-Gallés, 1997), sublexical representations (Cutler et al., 1989; 1992), grammaticality judgments (Weber-Fox and Neville, 1996), and speech production (Flege, Munro, and MacKay, 1995). Possibly, the fact that the cortical representations for the first and second languages tend to span overlapping areas with increased proficiency cannot be taken to mean equivalent competence. As Perani and colleagues state:

A possible interpretation of what brain imaging is telling us is that in the case of low proficiency individuals, the brain is recruiting multiple, and variable, brain regions, to handle as far as possible the dimensions of the second language, which are different from the first language. As proficiency increases, the highly proficient bilinguals use the same neural machinery to deal with the first and the second languages. However, this anatomical overlap cannot exclude that this brain network is using the linguistic structures of the first language to assimilate less than perfectly the dimensions of the second language.

Another inconsistency will have to be explained in future work. We know from several studies (e.g., Cohen et al., 1997; Kaas, 1995; Rauschecker, 1997; Sadato et al., 1996) that changing the nature and distribution of sen-

FIGURE 62.4 Intersubject variability in the cortical representation of language is greater for the second than for the first language. Each bar represents an anatomical region of interest (left and right hemisphere). Its length represents the average active volume (in square millimeters) in that region. Its color reflects the number of subjects in which that region was active. (Adapted from Dehaene et al., 1997.)

sory input can result in important modifications of the cortical maps, even in adult organisms. However, people do not reach native performance in a second language, despite massive exposure, training, and motivation. Can we reconcile cortical plasticity with behavioral rigidity?

Yet another area in great need of more research is the functional significance of activation maps in general. Consider the work by Neville and her colleagues on the representation of American Sign Language (ASL) in deaf and hearing native signers. These authors carried out an fMRI study and showed that ASL is bilaterally represented in both populations while written English is basically represented in the left hemisphere of the hearing signers (who were also native speakers of English). Hickok, Bellugi, and Klima (1996) studied 23 native

speakers of ASL with unilateral brain lesions and found clear and convincing evidence for a left-hemispheric dominance, much like the one found in speakers of natural languages. This leaves us in a dilemma: Either we assert that it is not easy to draw functional conclusions from activation maps, and/or we have to posit that ASL is not a natural language.

Mapping the higher cognitive functions to neural networks is an evolving skill. In the near future, we expect to witness a trend toward a more exhaustive study of a given function in a single subject. For instance, each volunteer could be tested several times to investigate in detail how language competence is organized and represented in his/her cortex. This should help us to elucidate several of the seemingly paradoxical findings we reported above. However things evolve, it is clear that when we understand these issues in greater depth, we will be able to make gigantic leaps in our understanding of development.

Conclusion

We have presented data drawn from experimental psychology, infant psychology, and brain-imaging to propose another way of addressing the study of development—this, to illustrate an approach to the study of development now gaining in support. By bringing together some of the areas that jointly clarify how the human mind gains access to language, logic, mathematics, and other such recursive systems, we can begin to answer several fundamental questions: (1) Why is the acquisition of some capacities possible for human brains and not for the brains of other higher vertebrates? (2) Are there skills that can be acquired more naturally and with a better outcome before a certain age? (3) Does the acquisition of some skill facilitate the acquisition of similar skills in older organisms—those who would normally show little disposition to learn “from scratch”? The need to answer such questions is the essence of many developmental research programs. The fact that questions like these are being asked has implications for the cognitive psychologist and cognitive neuroscience. Cognitive psychologists are becoming increasingly aware that they must conceive of development as a critical aspect of cognitive neuroscience. If, for instance, there are time schedules to naturally learn certain skills, the joint study of the time course of development and the concurrent maturation of neural structures may tell us which neural structures are responsible for the acquisition of which capacities. Coupled with brain-imaging and neuropsychological data, these facts may help us to understand better the mapping between neural structure and cognitive function. One may call such a study the “neuropsychology of the normal.”

In concluding, we dispute the notion that the acquisition of mental abilities can be sufficiently studied by looking only at growing children. We suggest that to understand the mechanisms responsible for change, one must first specify the normal envelope of stable states and the species-specific endowment; then we can go on to develop a theory of acquisition that accounts for the mapping from the initial to the stable state. Many different disciplines will have to participate in achieving this goal. Neuroscience has made many discoveries that are essential to the understanding of development; in particular, brain-imaging studies may bring in a new perspective to the research of growth and development. Thus, rather than making the study of development an autonomous part of cognition, we conceive of it as a unique source of information that should be an integral component of cognitive psychology.

ACKNOWLEDGMENTS We wish to thank the Human Frontiers Science Programme, Human Capital and Mobility Programme, the Direction de la Recherche, des Etudes, et de la Technologie, and the Franco-Spanish grant.

NOTES

1. There are some areas—e.g., the anterior poles of the temporal lobes and Brodmann 8—that had not often been related to language processing by classical neuropsychology.
2. Interestingly, the left inferior frontal gyrus, the left middle temporal gyrus, and the inferior left parietal lobule were more active when subjects were listening to Japanese compared to backward Japanese. These activations could mirror the subjects' attempt to store the input as meaningless phonological information in auditory short-term memory (see Paulesu, Frith, and Frackowiak, 1993). Perani and colleagues observed that the left middle temporal gyrus activation appeared only when subjects were listening to speech, regardless of whether they understood the stories, but not when listening to backward speech, an unnatural stimulus. The authors suggest that the left middle temporal gyrus is highly attuned to the processing of the sound patterns of any natural language.

63 The Cognitive Neuroscience of Language Acquisition

KARIN STROMSWOLD

ABSTRACT This chapter reviews findings from several research areas—normal language acquisition, learnability theory, developmental and acquired language disorders, and language acquisition after the critical period—indicating that the ability to acquire language is the result of innate brain mechanisms. It is possible that infants' brains are predisposed to perceive categorically such stimuli as phonemes, words, syntactic categories, and phrases, and this predisposition allows children to acquire language rapidly and with few errors.

Because the ability to learn a language is a uniquely human ability, language acquisition is an important topic in cognitive neuroscience. Perhaps the most fundamental question about language and language acquisition is the extent to which the ability to learn language is the result of innate mechanisms or predispositions (henceforth referred to as innate abilities). Innate abilities often share certain characteristics. An innate ability is usually present in all normal individuals. Its acquisition tends to be uniform and automatic, with all normal individuals going through the same stages at the same ages, without specific instruction. There may be a critical period for successful acquisition. The ability is likely to be functionally and anatomically autonomous or modular. Finally, the trait may be heritable.

Although these characteristics are by no means definitive, they can be used to evaluate traits that may be innate. Consider, for example, the ability to walk and the ability to knit. The ability to walk exhibits most of the hallmarks of innate abilities, and is presumably innate; but the ability to knit exhibits few of these hallmarks, and is presumably not innate. If children's brains are innately predisposed to learn language, then given adequate exposure to language, all children with normal brains should, without instruction, learn language in a relatively uniform way, just as normal vision develops given adequate exposure to visual stimuli (Hubel and Wiesel, 1970). But if the ability to learn language is not innate, instruction may be necessary, the course of acquisition may vary greatly from person to person (per-

haps as a function of the quality of instruction), and there may be no critical period for acquisition.

Even if the ability to learn language is the result of innate mechanisms and predispositions, another question remains: Are these mechanisms specific to language and language acquisition (e.g., Chomsky, 1981, 1986; Pinker, 1994) or are they also involved in tasks and abilities that are not linguistic (e.g., Karmiloff-Smith, 1991; Elman et al., 1996)? If the ability to acquire language is the result of innate mechanisms used solely for language and language acquisition, language may be functionally and anatomically autonomous or modular from other abilities, in which case developmental and acquired lesions may specifically impair or spare the ability to learn language. Conversely, if general-purpose mechanisms are involved in language acquisition, we would not expect to find evidence of the functional or anatomical modularity of language or language acquisition.

Language development

LINGUISTICS AND THE UNIVERSAL FEATURES OF LANGUAGE Superficially, learning to talk differs from learning to walk in that children are capable of learning many different languages, but just one basic walk. If children really are predisposed to learn all human languages, then all languages must be fundamentally the same. In fact, linguists have discovered that, although some languages seem to differ radically from other languages (e.g., Turkish and English), in essential ways all human languages are remarkably similar to one another (Chomsky, 1981, 1986; Croft, 1990).

Generative linguists usually assume that language involves rules and operations that have no counterparts in nonlinguistic domains and that the ability to use and acquire language is part of our innate endowment. For example, within principles-and-parameters (P&P) generative theory (Chomsky, 1981, 1986), all languages are said to share a common set of grammatical principles. Differences among languages result from the different parametric values chosen for those principles. According to P&P theory, at some level, children are born knowing

the principles that are universal to all languages (Universal Grammar); thus, to learn a particular language, all they must do is learn the vocabulary and parametric settings of that language. Similarly, within another generative linguistic theory—optimality theory (OT)—the same universal constraints operate in all languages, and languages differ merely in the ranking of these constraints (Prince and Smolensky, 1993). According to OT, children are born “knowing” the universal constraints; thus, to learn a particular language, all children must do is learn the vocabulary and ranking of constraints for that language (Tesar and Smolensky, 1996). Linguists working within the functionalist tradition (e.g., Foley and Van Valin, 1984) are more likely to assume that language shares properties with nonlinguistic abilities, and that operations used in language acquisition are used in other, nonlinguistic domains (e.g., Bates and MacWhinney, 1982; Budwig, 1995; Van Valin, 1991).

UNIFORMITY IN LANGUAGE ACQUISITION Within a given language, the course of language acquisition is remarkably uniform (Brown, 1973).¹ Most children say their first referential words at 9 to 15 months (Morley, 1965; Benedict, 1979; Fenson et al., 1994; Huttenlocher and Smiley, 1987), and for the next 6–8 months, children typically acquire single words fairly slowly until they have acquired approximately 50 words. For most children acquiring English, the majority of their first 50 words are labels for objects (e.g., *cookie, mother, father, bottle*) with a few action verbs (*eat, come, go*), social terms (*good-bye, hello*), and prepositions (*up, down*) rounding out the list (Nelson, 1973; Bates et al., 1994; Benedict, 1979). Once children have acquired 50 words, their vocabularies often increase rapidly (e.g., Reznick and Goldfield, 1992; Benedict, 1979; Mervis and Bertrand, 1995), expanding by 22 to 37 words per month (Benedict, 1979; Goldfield and Reznick, 1990).

At around 18 to 24 months, children learning morphologically impoverished languages such as English begin combining words to form two-word utterances such as *want cookie, play checkers, and big drum* (Brown, 1973). During this two-word stage, the vast majority of children’s utterances are legitimate portions of sentences in the language they are learning. Thus, in English—a language that has restricted word order—children will say *want cookie* but not *cookie want* (Brown, 1973) and *he big* but not *big he* (Bloom, 1990). Children acquiring such morphologically impoverished languages gradually begin to use sentences longer than two words; but for several months, their speech often lacks phonetically unstressed functional category morphemes such as determiners, auxiliary verbs, and verbal and nominal inflectional endings (Brown, 1973; Mills, 1985; Schieffelin,

1985). Representative utterances during this period include *Sarah want cookie, Where Humpty Dumpty go?*, and *Adam write pencil*. Children’s early speech is often described as “telegraphic” (Brown, 1973) because it resembles the way adults speak when words are at a premium, as in a telegram. Gradually, omissions become rarer until children are between three and four years old, at which point the vast majority of English-speaking children’s utterances are completely grammatical (Stromswold, 1990a,b, 1994b). Children who are acquiring languages like Turkish, which have rich, regular, and perceptually salient morphological systems, generally begin to use functional category morphemes at a younger age than children acquiring morphologically poor languages (Aksu-Koc and Slobin, 1985; Berman, 1986; Peters, 1995). For example, in striking contrast to the telegraphic speech of English-speaking children, Turkish-speaking children often begin to produce morphologically complex words before they begin to use multiword utterances (Aksu-Koc and Slobin, 1985).²

Within a given language, children master the syntax (grammar) of their language in a surprisingly similar manner (Brown, 1973). For example, children acquire the 14 grammatical morphemes of English in essentially the same order (Brown, 1973; deVilliers and deVilliers, 1973). Similarly, all 15 of the children I studied acquired the 20-odd English auxiliary verbs in essentially the same order (Stromswold, 1990a). The order in which these 15 children acquired complex constructions—questions, negative constructions, passives, datives, exceptional-case-marking constructions, embedded sentences, preposition-stranding constructions, causative constructions, small clause constructions, verb-particle constructions, and relative clauses constructions—was also extremely regular (Stromswold, 1988, 1989a,b, 1990a,b, 1992, 1994b, 1995; Stromswold and Snyder, 1995; Snyder and Stromswold, 1997). Finally, to a remarkable degree, within and across languages, children make certain types of mistakes and not others.

ACQUISITION OF SYNTACTIC CATEGORIES In order to acquire their language, children must not only learn the meanings of words like *cat* and *eat*, they must also learn that words like *cat* are nouns and words like *eat* are verbs. That is, they must learn the categorical membership of words. This is critical because whether a syntactic or morphological rule applies to a particular word depends on its categorical membership, not on its meaning. Consider, for example, the sentence *Linus cratomizes Lucy*: Any speaker of English automatically knows that *Linus* is the grammatical subject of the sentence (because, within an intonational clause, it is in preverbal position), *Lucy* is the grammatical object (because it is in

postverbal position), and the nonsense word *cratomize* is a lexical verb. Even without knowing what *cratomize* means, an English speaker automatically knows that its progressive form is *cratomizing* and that its past tense form is *cratomized*; that *do*-support is required to ask a standard matrix question (e.g., *Did Linus cratomize Lucy?* and not **Cratomized Linus Lucy?*³ or **Linus cratomized Lucy?*) or negate an utterance (e.g., *Linus didn't cratomize Lucy* and not **Linus cratomized not Lucy*, **Linus not cratomized Lucy*); and that the grammatical subject precedes rather than follows *cratomize* in simple declarative utterances (e.g., *Linus cratomizes Lucy* and not **cratomizes Linus Lucy*). The fact that English speakers know the syntactic and morphological behavior of *cratomize* without having the slightest idea what *cratomize* means demonstrates that categorical membership and not meaning determines syntactic and morphological behavior. A central question in the field of language acquisition is how children learn the categorical membership of words. For adults, the answer is simple. Even from the single sentence *Linus cratomizes Lucy*, adults recognize that *cratomize* is clearly a verb—it appears after the grammatical subject *Linus* and before the object *Lucy*, has the third-person verbal inflection *-s*, and exhibits other verb-like properties. The answer is much trickier for children.

How do children learn which words are verbs if they don't know what properties are typical of verbs? And how can they learn the properties of verbs if they don't know which words are verbs? One simple possibility is that every verb in every human language shares some readily accessible property for which children are innately predisposed to look. Unfortunately, no such property seems to exist. Instead, infants probably rely on a combination of cues—prosodic, semantic, and correlational—to learn which words are nouns and which are verbs (Pinker, 1987). Infants may, for example, use prosodic cues such as changes in fundamental frequency and lengthening to help determine where major clausal and phrasal boundaries are. Combined with knowledge of the universal properties of clauses and phrases (e.g., that verbs are contained within verb phrases and sentential clauses contain noun phrases and verb phrases), this could help children learn which words are verbs (Jusczyk et al., 1992; Jusczyk and Kemler Nelson, 1996; Morgan and Demuth, 1996). Infants might also set up an enormous correlation matrix in which they record all of the behaviors associated with words; in that case, categories are the result of children noticing that certain behaviors tend to be correlated. Thus, having noticed that certain words often end in *-ing*, *-ed*, or *-s*, frequently occur in the middle of sentences, and rarely appear in the beginning of a sentence, children sort out these words as a verb category (see Maratsos and Chalkley, 1981). The problem with the notion of a simple, un-

constrained, and unbiased correlational learner is the infinite number of correlations that children must consider, most of which will never appear in any language (Pinker, 1984, 1987). If infants are born “knowing” that, in language, objects are expressed by nouns, physical actions by verbs, and attributes by adjectives, infants could infer that words referring to physical objects are nouns, words referring to actions are verbs, and words referring to attributes are adjectives. They could learn the properties of nouns and verbs from these semantically prototypical cases, a process often referred to as “semantic bootstrapping” (see Pinker, 1984, 1987).

ACQUISITION OF AUXILIARY AND LEXICAL VERBS

The paradox of syntax acquisition is this: Unless children basically know what they have to learn before they begin, they cannot successfully learn the grammar of their language. However, even if it is demonstrated that children do indeed have innate mechanisms for learning the categorical membership of words, it is possible that such mechanisms are not specifically linguistic (for one such proposal, see Elman et al., 1996). To examine this proposition, we can look at the acquisition of auxiliary verbs and lexical verbs.

The acquisition of English auxiliary and lexical verbs is a particularly good test case because the two types of verbs are semantically, syntactically, and lexically similar; that is, a learner who has no knowledge of auxiliary and lexical verbs (i.e., a simple, unbiased correlational learner) is almost certain to confuse the two types of verbs. For many auxiliaries there is a lexical verb counterpart with an extremely similar meaning—e.g., the pairs *can/is able to*, *will/is going to*, and *must/have to*. Auxiliary and lexical verbs are syntactically similar in that both types often take verbal endings, follow subject noun phrases, and lack the grammatical properties of nouns, adjectives, and other syntactic categories. Moreover, auxiliary and lexical verbs typically have identical forms (e.g., copula and auxiliary forms of *be*, possessive and auxiliary forms of *have*, lexical verb and auxiliary forms of *do*). The remarkable degree of similarity can be appreciated by comparing pairs of sentences such as *he is sleepy* and *he is sleeping*, *he has cookies* and *he has eaten cookies*, and *he does windows* and *he does not do windows*.

The syntactic and morphological behavior of auxiliaries is extremely complex, and there are no obvious non-linguistic correlates for this behavior to aid in learning (Stromswold, 1990a). Without innate, specifically linguistic mechanisms, how could children correctly identify the 99 unique strings of auxiliaries that are acceptable in English from among $\sim 23!$ (2.59×10^{22}) unique strings of English auxiliaries?⁴ Descriptively, the basic restrictions on auxiliaries can be summarized as follows:

(Modal) (*have -en*) (progressive *be -ing*) (passive *be -en*)

Any or all of the auxiliaries are optional, but if they are present, they must occur in the above order. In addition, each auxiliary requires that the succeeding verb be of a certain form. Modal auxiliaries (e.g., *can*, *will*, *might*) require that the succeeding verb be an infinitival form (e.g., *eat*), perfect *have* requires that the succeeding verb be a perfect participle (e.g., *eaten*), progressive *be* requires that the succeeding verb be a progressive participle (e.g., *eating*), and passive *be* requires that the main verb be a passive participle (e.g., *eaten*). In addition, the first verbal element must be tensed in a matrix clause. Finally, matrix questions and negative statements are formed by inverting or negating the first auxiliary. If no auxiliary is present, *do*-support is required (see Stromswold, 1990a, and Stromswold, 1992, for additional restrictions and complications). Lexical and auxiliary verbs pose a serious learnability question (Baker, 1981; Pinker, 1984; Stromswold, 1989a, 1990a, 1992): How can children distinguish between auxiliary and lexical verbs before they learn the behavior of the two types of verbs, and how do children learn the two types of verbs' behaviors before they can distinguish between them?

If children don't distinguish between auxiliary and lexical verbs, they will generalize what they learn about one type of verb to the other type of verb. This will result in rapid learning. It will also lead children to make errors that can be set right only by negative evidence (information that a particular construction is ungrammatical). Unfortunately, parents don't seem to provide usable negative evidence (Brown and Hanlon, 1970; Marcus, 1993). Thus, if children do not distinguish between auxiliaries and lexical verbs, they are destined to make certain types of inflectional errors (e.g., **I aming go*, **I musts eat*) and combination errors involving multiple lexical verbs (e.g., **I hope go Disneyland*), negated lexical verbs (e.g., **I eat not cookies*), lone auxiliaries (e.g., **I must coffee*), and unacceptable combinations of auxiliaries (e.g., **I may should go*). They will also make word order errors, scrambling the order of lexical verbs and auxiliaries (e.g., **I go must*), scrambling the order of auxiliaries (e.g., **He have must gone*), and incorrectly inverting lexical verbs (e.g., *eats he meat?*). If, on the other hand, children have innate predispositions that allow them to distinguish between auxiliary and lexical verbs, they will not make these errors.

In order to test whether English-speaking children distinguish between auxiliary and lexical verbs, I searched the transcripts of 14 children's speech, examining by hand more than 66,000 utterances that contained auxiliaries (Stromswold, 1989a, 1990a). I found that the chil-

dren acquired the auxiliary system with remarkable speed and accuracy. In fact, I found no clear examples of the types of inflectional errors, combination errors, or word order errors they would have made if they confused auxiliary and lexical verbs. Thus, children seem to have innate, specifically linguistic mechanisms that allow them to distinguish between auxiliary and lexical verbs.

ERRORS, INSTRUCTION, AND THE AUTOMATICITY OF LANGUAGE One of the hallmarks of innate abilities is that they can be acquired without explicit instruction. This seems to be true for language. Parents do correct their children when they make errors that affect the meaning of utterances, but they do not reliably correct grammatical errors (Brown and Hanlon, 1970; Marcus, 1993). And even when parents do try to correct grammatical errors, their efforts are often in vain (McNeill, 1966). Furthermore, correction is not necessary for lexical and syntactic acquisition because some children who are unable to speak (and hence cannot be corrected by their parents) have normal receptive language (Stromswold, 1994a). If teaching and correction are necessary for language development, it should not be possible for children to have impaired production and intact comprehension. I have studied the language acquisition of a young child who is unable to speak. Despite the fact that he had essentially no expressive language (he could say only a handful of phonemes), his receptive language was completely intact. At age 4, he was able to distinguish between reversible active and passive sentences (correctly distinguishing the meanings conveyed by sentences such as *The dog bit the cat*, *The cat bit the dog*, *The dog was bitten by the cat*, and *The cat was bitten by the dog*) and to make grammaticality judgments (e.g., correctly recognizing that *What can Cookie Monster eat?* is grammatical whereas **What Cookie Monster can eat?* is not) (see Stromswold, 1994a).

Children learn language quickly, never making certain types of errors that seem very reasonable (e.g., certain types of auxiliary errors). But as Pinker (1989) points out, children are not perfect: They do make certain types of errors. They overregularize inflectional endings, saying *eated* for *ate* and *mouses* for *mice* (Pinker, 1989). They make lexical errors, sometimes passivizing verbs such as *die* that do not passivize (e.g., *He get died*; from Pinker, 1989). They also make certain types of syntactic errors, such as using *do*-support when it is not required (e.g., *Does it be around it?* and *This doesn't be straight*; Stromswold, 1990b, 1992) and failing to use *do*-support when it is required (e.g., *What she eats?* Stromswold, 1990a, 1994b). What do these errors tell us? First, they confirm that children use language productively and are not merely repeating what they hear their par-

ents say because parents do not use these unacceptable forms (Pinker, 1989). These errors may also provide an insight into the peculiarities of languages. For example, children's difficulty with *do*-support suggest that *do*-support is not part of universal grammar, but rather is a peculiar property of English (Stromswold, 1990a,b, 1994b).

Finally, these errors may provide insight into the types of linguistic categories that children are predisposed to acquire. Consider, for example, the finding that children overregularize lexical *be*, *do*, and *have*, but they never overregularize auxiliary *be*, *do*, and *have* (Stromswold, 1989a, 1990a, in press-a). The fact that children say sentences like **She beed happy* but not **She beed smiling* indicates that children not only distinguish between auxiliary verbs and lexical verbs, but they treat the two types of verbs differently. What kind of innate learning mechanism could result in children's overregularizing lexical verbs but not the homophonous auxiliaries? One possibility is that children have innate learning mechanisms that specifically cause them to treat auxiliary and lexical verbs differently. Unfortunately, there are problems with this explanation. Although many languages contain words that are semantically and syntactically similar to English auxiliaries (Steele, 1981), and all languages are capable of making the semantic and syntactic distinctions that in English are made by auxiliaries, some languages either lack auxiliaries (instead making use of inflectional affixes) or make no distinction between auxiliaries and lexical verbs. Given that not all languages contain easily confused auxiliary verbs and lexical verbs, the existence of a specific innate mechanism for making this distinction seems unlikely. In addition, hypothesizing a specific innate mechanism has little explanatory power—it explains nothing beyond the phenomena that led us to propose its existence.

Alternatively, children's ability to distinguish between auxiliary and lexical verbs might reflect a more general ability to distinguish between functional categories (determiners, auxiliaries, nominal and verbal inflections, pronouns, etc.) and lexical categories (nouns, verbs, adjectives, etc.). Lexical categories are promiscuous: They freely admit new members (*fax*, *modem*, *email*, etc.) and the grammatical behavior of one member of a lexical category can fairly safely be generalized to another member of the same lexical category. Functional categories are conservative: New members are not welcome and generalizations, even within a functional category, are very dangerous (see Stromswold, 1990a, 1994c). Innate mechanisms that specifically predispose children to distinguish between lexical and functional categories have a number of advantages over a specific mechanism for auxiliary and lexical verbs. Unlike the auxiliary/lexical verb distinction, the lexical/functional category distinction is

found in all human languages; thus, mechanisms that predispose children to distinguish between lexical categories and functional categories are better candidates, a priori, for being innate. In addition, research on speech errors (e.g., Garrett, 1976), neologisms (Stromswold, 1994c), parsing (e.g., Morgan and Newport, 1981), linguistic typology (e.g., Croft, 1990), aphasia (e.g., Goodglass, 1976), and developmental language disorders (e.g., Guilfoyle, Allen, and Moss, 1991) as well as findings from event-related potentials (Neville, 1991; Holcomb, Coffey, and Neville, 1992; Neville et al., 1993; Neville, 1995; Neville, Mills, and Lawson, 1992) and functional magnetic resonance imaging (Neville et al., 1994) all point to the importance of the lexical/functional distinction.

Innate mechanisms that predispose children to distinguish between lexical and functional categories would also help them to distinguish between auxiliary and lexical verbs, as well as pronouns and nouns, determiners and adjectives, verbal stems and verbal inflections, and other pairs of lexical and functional categories. If these innate mechanisms predispose children to distinguish between syntactic categories that allow for free generalization (lexical categories) and those that do not (functional categories), this would explain why children overregularize lexical *be*, *do*, and *have* but not auxiliary *be*, *do*, and *have*. It would also help explain why children are able to learn language so rapidly and with so few errors; that is, such a learning mechanism would permit children to generalize only where it is safe to do so (i.e., within a lexical category). Computationally, the difference between lexical and functional categories might be expressed as the difference between rule-based generalizations and lists, or within a connectionist framework, between network architectures that have different degrees and configurations of connectivity (see Stromswold, 1994c).

Role of linguistic input and critical periods in language acquisition

PIDGINS The uniformity of language development under normal conditions could be due to biological or environmental processes. One way to investigate the relative roles of biological and environmental factors is to investigate the linguistic abilities of children whose early language environments are suboptimal. Studies of creolization provide compelling evidence that human children are innately endowed with the ability to develop a very specific kind of language even when they receive minimal input. Creolization may occur, for example, when migrant workers who speak a variety of languages must work together and their only common language is a simplified pidgin of another, dominant language. Pidgins typically consist of fixed phrases and pantomimes and

can express only basic needs and ideas. Bickerton (1981, 1984), studying the language of second-generation pidgin speakers (i.e., the children of pidgin speakers), has found that they use a creolized language that is much richer than their parents' pidgin. For example, the creolized language of second-generation pidgin speakers includes embedded and relative clauses, aspectual distinctions, and consistent word order, despite the absence of such features in the input (pidgin) language (Bickerton, 1981, 1984). Thus, second-generation pidgin speakers "invent" a language that is more complex than the pidgin language to which they are exposed.

HOMESIGN How minimal can the input be? Although children who hear only pidgin languages have impoverished input, there are even more extreme situations of language deprivation. Consider deaf children born to hearing parents who do not use or expose their infants to sign language but otherwise provide normal care (i.e., their parents neither abuse nor neglect them). Such children are deaf isolates—they receive essentially no linguistic input. Deaf isolates offer us a fascinating picture of the limits of the innate endowment to create language, and hence a glimpse at the early unfolding of language in all infants. As infants and toddlers, deaf isolates seem to achieve the same early-language milestones as hearing children. Right on schedule, at around 6–8 months, deaf isolates begin to "babble"—they make hand motions analogous to the spoken babbling of hearing babies. They invent their first signs at about the same age that hearing children produce their first words. They even begin to form short phrases with these signs, also on a comparable schedule to hearing children (Goldin-Meadow and Mylander, 1984, 1998; Morford, 1996). Thus, these early linguistic milestones are apparently able to unfold even without linguistic input. Preliminary research on older deaf isolates indicates that their gestural communication systems are more sophisticated than those used by young deaf isolates, although even their systems do not exhibit the complexity of natural sign languages (Coppola et al., 1998).

The ability to learn language appears to be the result of innate processes; however, childhood language exposure is necessary for normal language development, just as the ability to see is innate but visual stimulation is necessary for normal visual development (Hubel and Wiesel, 1970). The hypothesis that exposure to language must occur by a certain age in order for language to be acquired normally is called the critical (or sensitive) period hypothesis. The critical period for language acquisition is generally believed to coincide with the period of great neural plasticity and is often thought to end at or sometime before the onset of puberty (see Lenneberg, 1967).

WILD CHILDREN Skuse (1984a,b) reviewed nine well-documented cases of children who had been raised under conditions of extreme social and linguistic deprivation for 2.5 to 12 years. All of these cases involved grossly impoverished environments, frequently accompanied with malnourishment and physical abuse. At the time of discovery, the children ranged in age from 2.5 years to 13.5 years, had essentially no receptive or expressive language, and were globally retarded in nonlinguistic domains. The six children who eventually acquired normal or near-normal language function were all discovered by age 7 and had no signs of brain damage. Of the three children who remained language-impaired, one was discovered at age 5 but had clear evidence of brain damage (Davis, 1940, 1947) and one was discovered at age 3.5 but had organic abnormalities not attributable to extreme deprivation (Skuse, 1984a). Genie, the third child with persistent linguistic impairments, is remarkable both for having the most prolonged period of deprivation (12 years) and, at almost 14 years of age, for being the oldest when discovered (Curtiss, 1977). Neuropsychological testing suggests that Genie does not have the expected left hemisphere lateralization for language. It is tempting to conclude that Genie's failure to acquire normal language and her anomalous lateralization of language function are both the result of her lack of exposure to language prior to the onset of puberty; however, it is possible that cortical anomalies in the left hemisphere are the cause of her anomalous lateralization and her failure to acquire language (Curtiss, 1977).

DEAF ISOLATES As Curtiss (1977, 1989) points out, it is impossible to be certain that the linguistic impairment observed in children such as Genie are the result of linguistic isolation, and not the result of social and physical deprivation and abuse. Curtiss (1989) has described the case of Chelsea, a hearing-impaired woman who had essentially no exposure to language until age 32. Unlike Genie, Chelsea did not experience any social or physical deprivation. Chelsea's ability to use language (particularly syntax) is at least as impaired as Genie's, an observation consistent with the critical period hypothesis (Curtiss 1989). To test whether there is a critical period for first language acquisition, Newport and colleagues (Newport, 1990) have studied the signing abilities of deaf people whose first exposure to American Sign Language (ASL) was at birth (native signers), before age 6 (early signers), or after age 12 (late signers). Consistent with the critical period hypothesis, even after 30 years of using ASL, on tests of morphology and complex syntax, native signers outperform early signers, who in turn outperform late signers (Newport, 1990).

SECOND LANGUAGE ACQUISITION To test whether there is a critical period for second language acquisition, Johnson and Newport (1989) studied the English abilities of native speakers of Korean or Chinese who first became immersed in English between the ages of 3 and 39. For subjects who began to learn English before puberty, age of English immersion correlated extremely highly with proficiency with English syntax and morphology, whereas no significant correlation was found for subjects who began to learn English after puberty (Johnson and Newport, 1989).

Evidence from studies of children such as Genie, deaf isolates, and people who acquire a second language suggests that the ability to acquire language diminishes with age. Other research has shown that complete language recovery rarely occurs if a left hemisphere lesion occurs after age 5 and substantial recovery rarely occurs if a lesion is acquired after the onset of puberty. Moreover, subtle tests of linguistic abilities reveal that native fluency in a language is rarely attained if one's first exposure to that language occurs after early childhood and competence in a language is rarely attained if first exposure occurs after the onset of puberty. This is consistent with Hubel and Wiesel's (1970) finding that normal visual development requires visual stimuli during a critical period of neural development and suggests that neural fine-tuning is a critical to normal language acquisition—a fine-tuning that can occur only with exposure to language during a certain time period.

Language acquisition and brain development

We have argued that the ability to learn language is the result of innate, language-specific learning mechanisms. And we have investigated the extent to which normal language development depends on receiving appropriate linguistic input during a critical window of cognitive (and presumably neuronal) development. Here we review the neurobiological evidence supporting the idea that language is the result of innate, language-specific learning mechanisms.

DEVELOPMENT OF LANGUAGE REGIONS OF THE BRAIN Lenneberg (1967) notwithstanding, the language areas of the human brain appear to be anatomical and functionally asymmetrical at or before birth. Anatomically, analyses of fetal brains reveal that the temporal plane is larger in the left hemisphere than in the right hemisphere (Wada, Clarke, and Hamm, 1975).⁵ Development of the cortical regions that subserve language in the left hemisphere consistently lags behind the development of the homologous regions in the right hemisphere. The right temporal plane appears during the

thirtieth gestational week, while the left temporal plane appears about 7–10 days later (Chi, Dooling, and Gilles, 1977). Even in infancy, dendritic development in the region around Broca's area on the left lags behind that found in the homologous region on the right (Scheibel, 1984). Event-related potential (ERP) and dichotic listening experiments suggest that the left hemisphere is differentially sensitive for speech from birth (for a review, see Mehler and Christophe, 1995).

Relatively few studies have investigated the neural bases of lexical or syntactic abilities in neurologically intact children. Among these is the work of Molfese and colleagues (Molfese, 1990; Molfese, Morse, and Peters, 1990), who taught infants as young as 14 months labels for novel objects, then compared the ERPs when the objects were paired with correct and incorrect verbal labels. A late-occurring response was recorded in the left hemisphere electrode sites when the correct label was given but not when an incorrect label was given. Similarly, an early-occurring response was recorded bilaterally in the frontal electrodes when the correct label was given, but not when an incorrect label was given. In recent work, Mills, Coffey-Corina, and Neville (1997) recorded the ERPs when children between 13 to 20 months of age listened to words meanings they knew, words whose meanings they did not know, and backward words. They found that the ERPs differed as a function of meaning within 200 ms of word onset. Between 13 and 17 months, the ERP differences for known versus unknown words were bilateral and widely distributed over anterior and posterior regions. By 20 months, the differences were limited to left temporal and parietal regions.

In another ERP study, Holcomb, Coffey, and Neville (1992) found no clear evidence prior to age 13 of the normal adult pattern of greater negativity in the left hemisphere for semantically plausible sentences (e.g., *We baked cookies in the oven*) and greater negativity in the right hemisphere for semantically anomalous sentences (e.g., *Mother wears a ring on her school*). In addition, the negative peak associated with semantic anomalies (the N400) was later and longer in duration for younger subjects than older subjects. Holcomb, Coffey, and Neville (1992) also found evidence that the normal adult pattern of a left anterior N280 waveform associated with functional category words and a bilateral posterior N350 waveform associated with lexical category words (Neville, Mills, and Lawson, 1992) does not develop until around puberty. Four-year-old children typically have N350 response to both lexical and functional words. By 11 years of age, the N350 is greatly reduced or absent for functional category words. It isn't until approximately 15 years of age that functional category words result in a clear N280 response with adult-like distribution

(Holcomb, Coffey, and Neville, 1992). In summary, simple linguistic stimuli (e.g., lexical words) appear to evoke similar types of electrical activity in young children's and adult brains; but for more complicated linguistic stimuli involving grammatical aspects of language, children's ERPs may not closely resemble adult ERPs until around puberty. That the critical period for language acquisition (especially syntax) ends at approximately the same age that children develop adult-like ERPs for grammatical aspects of language is intriguing. It is also suggestive, raising the possibility that once adult-like neural pathways and operations are acquired, neural plasticity is so greatly reduced that the ability to acquire all but the most rudimentary aspects of syntax is lost.

MODULARITY OF LANGUAGE ACQUISITION With some notable exceptions, most of what is known about the relationship between brain development and lexical and syntactic development has come from studying language acquisition by children who have developmental syndromes or brain lesions. If, as was argued earlier, language acquisition involves the development of specialized structures and operations having no counterparts in nonlinguistic domains, then it should be possible for a child to be cognitively intact and linguistically impaired or to be linguistically intact and cognitively impaired. But if language acquisition involves the development of the same general symbolic structures and operations used in other cognitive domains, then dissociation of language and general cognitive development should be impossible. Recent studies suggest that language development is selectively impaired in some children with specific language impairment (SLI) and selectively spared in children who suffer from disorders such as Williams syndrome.

Specific language impairment SLI encompasses developmental disorders characterized by severe deficits in the production and/or comprehension of language that cannot be explained by hearing loss, mental retardation, motor deficits, neurological or psychiatric disorders, or lack of exposure to language. Because SLI is a diagnosis of exclusion, SLI children are a very heterogeneous group. This heterogeneity can and does affect the outcome of behavioral and neurological studies, with different studies of SLI children frequently reporting different results depending on how SLI subjects were chosen. The exact nature of the etiology of SLI remains uncertain (for a review, see Leonard, 1998; Stromswold, 1997), with proposals including impoverished or deviant linguistic input (Cramblit and Siegel, 1977; Lasky and Kloppe, 1982), transient, fluctuating hearing loss (Bishop and Edmundson,

1986; Gordon, 1988; Gravel and Wallace, 1992; Teele et al., 1990), impairment in short-term auditory memory (Graham, 1968, 1974; Rapin and Wilson, 1978), impairment in auditory sequencing (Efron, 1963; Monsee, 1961), impairment in rapid auditory processing (Tallal and Piercy, 1973a,b, 1974), general impairment in sequencing (Poppen et al., 1969), general impairment in rapid sensory processing (Tallal, 1990), general impairment in representational or symbolic reasoning (Johnston and Weismer, 1983; Kahmi, 1981; Morehead and Ingram, 1973), general impairment in hierarchical planning (Cromer, 1983), impairments in language perception or processing [e.g., the inability to acquire aspects of language that are not phonologically salient (Leonard, 1989, 1994; Leonard, McGregor, and Allen, 1992)], impairments in underlying grammar [e.g., the lack of linguistic features such as tense and number (Crago and Gopnik, 1994; Gopnik, 1990a,b; Gopnik and Crago, 1991), the inability to use government to analyze certain types of syntactic relations (van der Lely, 1994), and the inability to form certain types of agreement relations (Clahsen, 1989, 1991; Rice, 1994)], or some combination thereof. Some researchers have even suggested that SLI is not a distinct clinical entity, and that SLI children just represent the low end of the normal continuum in linguistic ability (Johnston, 1991; Leonard, 1991).

At the neural level, the cause of SLI is also uncertain. Initially, it was theorized that children with SLI had bilateral damage to the perisylvian cortical regions that subserve language in adults (Bishop, 1987). Because SLI is not a fatal disorder and people with SLI have normal life spans, to date, only one brain of a possible SLI child has come to autopsy. Post-mortem examination of this brain revealed atypical symmetry of the temporal planes and a dysplastic microgyrus on the interior surface of the left frontal cortex along the inferior surface of the sylvian fissure (Cohen, Campbell, and Yaghai, 1989), findings similar to those reported in dyslexic brains by Geschwind and Galaburda (1987). It is tempting to use the results of this autopsy to argue—as Geschwind and Galaburda (1987) have for dyslexia—that SLI is the result of subtle anomalies in the left perisylvian cortex. However, the child whose brain was autopsied had a performance IQ of just 74 (verbal IQ 70); hence the anomalies noted on autopsy may be related to the child's general cognitive impairment rather than to her language impairment.

Computed tomography (CT) and magnetic resonance imaging (MRI) scans of SLI children have failed to reveal the types of gross perisylvian lesions typically found in patients with acquired aphasia (Jernigan et al., 1991; Plante et al., 1991). But CT and MRI scans have revealed that the brains of SLI children often fail to exhibit the normal pattern in which the left temporal plane

is larger than the right (Jernigan et al., 1991; Plante, 1991; Plante, Swisher, and Vance, 1989; Plante et al., 1991). Examinations of MRI scans have revealed that dyslexics are more likely to have additional gyri between the postcentral sulcus and the supramarginal gyrus than are normal readers (Leonard et al., 1993). Jackson and Plante (1997) recently performed the same type of gyrus morphology analyses on MRI scans of 10 SLI children, their parents, 10 siblings, and 20 adult controls.⁶ For the control group, 23% of the hemispheres showed an intermediate gyrus, whereas 41% of the hemispheres for SLI family members (probands, their siblings, and parents combined) showed an intermediate gyrus. However, affected family members did not appear to be more likely to have an intermediate gyrus than unaffected members. Clark and Plante (1995) compared the morphology of Broca's area in parents of SLI children and adult controls. Overall, parents of SLI children were no more likely to have an extra sulcus in the vicinity of Broca's area. However, parents with documented language impairments were more likely to have an extra sulcus than unaffected parents.

A number of researchers have studied the functional characteristics of SLI children's brains. Data from dichotic listening experiments (e.g., Arnold and Schwartz, 1983; Boliek, Bryden, and Obrzut, 1988; Cohen et al., 1991) and ERP experiments (e.g., Dawson et al., 1989) suggest that at least some SLI children have aberrant functional lateralization for language, with language present either bilaterally or predominantly in the right hemisphere. Single photon emission computed tomography (SPECT) studies of normal and language-impaired children have revealed hypoperfusion in the inferior frontal convolution of the left hemisphere (including Broca's area) in two children with isolated expressive language impairment (Denays et al., 1989), hypoperfusion of the left temporoparietal region and the upper and middle regions of the right frontal lobe in nine of twelve children with expressive and receptive language impairment (Denays et al., 1989), and hypoperfusion in the left temporo-frontal region of language-impaired children's brains (Lou, Henriksen, and Bruhn, 1990).

Courchesne and colleagues (1989) did not find any differences in ERP amplitude or latency between SLI adolescents and adults and age-matched controls. But in a subsequent study of school-age SLI children (Lincoln et al., 1995), they found that normal age-matched controls exhibited the normal pattern of larger amplitude N100s for more intense auditory stimuli intensity, while SLI subjects did not exhibit that pattern. This finding suggests the possibility of some abnormality in the auditory cortex of SLI children. Neville and colleagues (1993) compared the ERPs of SLI children and normal

age-matched controls for three tasks. In the first task, subjects pressed a button when they detected 1000-Hz tones among a series of 2000-Hz tones. In the second task, subjects were asked to detect small white rectangles among a series of large red squares. In the third task, children read sentences one word at a time and judged whether or not the sentences were semantically plausible (half of the sentences ended with a semantically appropriate word and half ended with a semantically inappropriate word). Overall, for the auditory monitoring task, the SLI children's ERPs did not differ from those of the control children. However, when the SLI children were divided into groups according to their performance on Tallal and Piercy's (1973a,b) auditory processing task, children who performed poorly on that task exhibited reduced-amplitude ERP waves over the anterior portion of the right hemisphere together with greater latency for the N140 component. In general, the SLI children had abnormally large N400s on the sentence task. As is typically seen with adults, the normal children's N400s for closed-class words were larger over the anterior left hemisphere than the anterior right hemisphere. However, the SLI children with the greatest morphosyntactic deficits did not exhibit this asymmetry.⁷

Despite decades of intensive and productive research on SLI, a number of fundamental questions about SLI remain unanswered. Researchers disagree about the etiology of SLI at a neural or cognitive level, and offer proposals ranging from a specific impairment in a circumscribed aspect of abstract linguistics to general cognitive/processing impairments due to environmental causes. Even among researchers who believe that SLI specifically affects linguistic competence, there is disagreement about what aspect of the underlying grammar is impaired. Furthermore, numerous studies have revealed that many (if not most) children with SLI exhibit nonlinguistic deficits, although some researchers argue that these nonlinguistic deficits are secondary to their primary linguistic impairments (for a review, see Leonard, 1998). A first step in seeking answers to these questions is to study more homogeneous subgroups of children diagnosed with SLI.⁸ In summary, although generally consistent with the hypothesis of a specific module for language and language acquisition, the emerging picture of SLI is not as "clean" as modularists might hope: SLI children are a heterogeneous group, and many (perhaps all) are not perfectly intact but for a damaged language module.

Williams syndrome Although mental retardation generally results in depression of language function (Rondal, 1980), researchers have reported that some mentally

retarded children have remarkably intact language. This condition has been reported in some children with hydrocephalus (Swisher and Pinsker, 1971), Turner's syndrome (Yamada and Curtiss, 1981), infantile hypercalcemia or Williams syndrome (Bellugi et al., 1992), and mental retardation of unknown etiology (Yamada, 1990).

Williams syndrome (WS) is a rare (1 in 25,000) genetic disorder involving deletion of portions of chromosome 7 around and including the elastin gene (Ewart et al., 1993a,b). People with WS often have particularly extreme dissociation of language and cognitive functions (Bellugi et al., 1992). Hallmarks of WS include microcephaly with a "pixie-like" facial appearance, general mental retardation with IQs typically in the 40s and 50s, delayed onset of expressive language, and "an unusual command of language combined with an unexpectedly polite, open and gentle manner" by early adolescence (Von Arman and Engel, 1964). In a recent study, the MacArthur Communicative Development Inventory (a parental report measure) was used to assess the earliest stages of language development for children with WS and children with Down syndrome (DS). This study revealed that WS and DS children were equally delayed in the acquisition of words, with an average delay of 2 years for both groups (Singer Harris et al., 1997). WS and DS children who had begun to combine words (mean age 46 months) did not differ significantly in language age (mean ages 23.7 months and 21 months, respectively). However, compared to the DS children, these older WS children had significantly higher scores on grammatical complexity measures and on mean length of utterance for their longest three sentences (Singer Harris et al., 1997). The gap in linguistic abilities of WS and DS children increases with age (Bellugi, Wang, and Jernigan, 1994). Although adolescents with WS use language that is often deviant for their chronological age and do poorly on many standardized language tests, they have larger vocabularies than do children of equivalent mental ages and speak in sentences that are syntactically and morphologically more complex and well-formed. In addition, WS adolescents and adults demonstrate good metalinguistic skills, such as the ability to recognize an utterance as ungrammatical and to respond in a contextually appropriate manner (Bellugi et al., 1992).

Volumetric analyses of MRI scans indicate that compared to normal brains, cerebral volume and cerebral gray matter of WS brains are significantly reduced in size and the neocerebellar vermal lobules are increased in size, with paleocerebellar vermal regions of low-normal size (Jernigan and Bellugi, 1994; Jernigan et al., 1993; Wang et al., 1992). To date only one WS brain

has come to autopsy (Galaburda et al., 1994). This brain had extensive cytoarchitectural abnormalities, including exaggeration of horizontal abnormalities within layers (most striking in area 17 of the occipital lobe), increased cell density throughout the brain, and abnormally clustered and oriented neurons. In addition, although the frontal lobes and most of the temporal lobes were relatively normal in size, the posterior forebrain was much smaller than normal. Galaburda and colleagues interpreted these findings as evidence of developmental arrest between the end of the second trimester and the second year of life. They further suggested that these findings may be related to hypercalcemia found in WS. Alternatively, elastin may have a direct, but hitherto undiscovered, neurodevelopmental function, in which case the macroscopic and microscopic abnormalities may be associated with the decreased levels of elastin in WS.

Early studies revealed that, although auditory ERPs for WS adolescents are similar in morphology, distribution, sequence, and latency to those of age-matched controls, WS adolescents display large-amplitude responses even at short interstimulus intervals, suggesting hyperexcitability of auditory mechanisms at the cortical level with shorter refractory periods (Neville, Holcomb, and Mills, 1989; Neville, Mills, and Bellugi, 1994). When WS subjects listened to spoken words, their ERPs had grossly abnormal morphology not seen in normal children at any age (Neville, Mills, and Bellugi, 1994). In contrast, the morphology of their ERPs for visually presented words was normal. Compared with normal subjects, WS subjects had larger priming effects for auditorily presented words, but priming effects for visually presented words were normal or smaller than those observed for normal subjects (Neville, Mills, and Bellugi, 1994). These results suggest that WS subjects' relative sparing of language function is related to hypersensitivity to auditorily presented linguistic material. To date no PET or SPECT studies of WS children have been reported. It will be interesting to learn from such studies whether it is the classically defined language areas in general or just primary auditory cortex in WS brains that become hyperperfused in response to auditory linguistic stimuli. In summary, although generally consistent with the hypothesis of specific module for language and language acquisition, the emerging picture of WS is not as "clean" as modularists might hope: Although WS adolescents and adults have better linguistic abilities than others with comparable IQs, their language is far from perfect and the mechanisms they use for language acquisition may not be the same as those used by normal children (see, for example, Karmiloff-Smith et al., 1997, 1998; Stevens and Karmiloff-Smith, 1997).

GENETIC BASIS OF LANGUAGE If the acquisition of language is the result of specialized structures in the brain and these linguistically specific structures are coded for by information contained in the genetic code, one might expect to find evidence for the heritability of language (see Pinker and Bloom, 1990; Ganger and Stromswold, 1998). But if language acquisition is essentially the result of instruction and involves no specifically linguistic structures, one should find no evidence of genetic transmission of language.

Familial aggregation studies A comprehensive review of family aggregation studies, sex ratio studies, pedigree studies, commingling studies, and segregation studies of spoken language disorders reveals that spoken language disorders have a strong tendency to aggregate in families (Stromswold, 1998). Stromswold (1998) reviewed 18 family aggregation studies of spoken language impairment (see table 63.1). In all seven studies that collected data for both probands and controls, the incidence of positive family history was significantly greater for probands than controls.⁹ In these seven studies, the reported incidence of positive family history for probands ranged from 24% (Bishop and Edmundson, 1986) to 78% (van der Lely and Stollwerck, 1996), with a mean incidence of 46% and a median incidence of 35%.¹⁰ For controls, positive family history rates ranged from 3% (Bishop and Edmundson, 1986) to 46% (Tallal, Ross, and Curtiss, 1989a), with a mean incidence of 18% and a median incidence of 11%.

Of all the studies of family aggregation Stromswold (1998) reviewed, eleven reported the percentage of probands' relatives who were impaired. For probands, the percentage of family members who were impaired ranged from 20% (Neils and Aram, 1986) to 42% (Tallal, Ross, and Curtiss, 1989a), with a mean impairment rate of 28% and median impairment rate of 26%. For controls, the percentage of family members who were impaired ranged from 3% (Neils and Aram, 1986) to 19% (Tallal, Ross, and Curtiss, 1989a), with a mean impairment rate of 9% and a median impairment rate of 7%. The incidence of impairment was significantly higher among proband relatives than control relatives in seven of the eight studies that made such a comparison.

Although data on familial aggregation suggest that some developmental language disorders have a genetic component, it is possible that children with language-impaired parents or siblings are more likely to be linguistically impaired themselves because they are exposed to deviant language (the deviant linguistic environment hypothesis, DLEH). Some studies have reported that mothers are more likely to use directive speech and less likely to use responsive speech when talking to their language-

impaired children than are mothers speaking to normal children (e.g., Conti-Ramsden and Friel-Patti, 1983; Conti-Ramsden and Dykins, 1991). However, children's language impairments may cause mothers to use simplified speech, rather than vice versa. That is, mothers of language-impaired children may use directive speech because they cannot understand their impaired children and their impaired children do not understand them if they use more complicated language. Furthermore, although within a fairly wide range, linguistic environment may have little or no effect on language acquisition by normal children (e.g., Heath, 1983), genetics and environment may exert a synergistic effect in children who are genetically at risk for developing language disorders. Such children may be particularly sensitive to subtly impoverished linguistic environments.

Despite the DLEH prediction that the most severely impaired children should come from families with the highest incidence of language impairments, Byrne, Willerman, and Ashmore (1974) found that children with profound language impairments were less likely to have positive family histories of language impairment than children with moderate language impairments. Similarly, Tallal and colleagues (1991) found no differences in the language abilities of children who did and did not have a positive family history of language disorders. According to the DLEH, the deficits exhibited by language-impaired children result from "copying" the ungrammatical language of their parents. Therefore, the DLEH predicts that language-impaired children should have the same type of impairment as that of their relatives. However, Neils and Aram (1986) found that 38% of parents with a history of a speech and language disorder said that their disorder differed from their children's disorder. According to the DLEH, parents with a history of spoken language impairment who are no longer impaired should be no more likely to have language-impaired children than parents with no such history. But Neils and Aram (1986) found that a third of the probands' parents who had a history of a spoken language disorder did not suffer from the disorder as adults. The DLEH predicts that all children with SLI should have at least one close relative with a language impairment; however, in the studies reviewed, an average of 58% of the language-impaired children had no first-degree relatives with impairments. If the DLEH is correct, birth order might affect the likelihood that a child will exhibit a language disorder. But birth order apparently affects neither the severity nor the likelihood of developing language disorders (see Tomblin, Hardy, and Hein, 1991). In our society, mothers typically have the primary responsibility for child-rearing; hence the DLEH predicts that the correlation of language status

should be greatest between mother and child. Contrary to this prediction, Tomblin (1989) found that among the family relations he studied (i.e., mother-child, father-child, male sibling-child, female sibling-child), the relationship was weakest between mother and child. Other studies that measured the ratio of impaired fathers to impaired mothers also report contra-DLEH results: The father:mother ratio has been reported as 2.7:1 (Tomblin and Buckwalter, 1994), 1.4:1 (Neils and Aram, 1986), and approximately 1:1 (Tallal, Ross, and Curtiss, 1989b; Whitehurst et al., 1991; Lewis, 1992).

Twin studies The influences of environmental and genetic factors on language disorders can be teased apart by comparing the concordance rates for language impairment in monozygotic (MZ) and dizygotic (DZ) twins. MZ and DZ twins share the same pre- and postnatal environment. Thus, if the concordance rate for a particular trait is greater for MZ than DZ twins, it probably reflects the fact that MZ twins share 100% of their genetic material while DZ twins share, on average, just 50% of their genetic material (for a review, see Eldridge, 1983). Stromswold (1996, in press-b) reviewed five studies that examined the concordance rates for written language disorders and four studies that examined the concordance rates for spoken

language disorders (see tables 63.2 and 63.3). In all nine studies, the concordance rates for MZ twin pairs were greater than those for DZ twin pairs, with the differences being significant in all but one study (Stevenson et al., 1987). In these studies concordance rates ranged from 100% (Zerbin-Rudin, 1967) to 33% (Stevenson et al., 1987) for MZ twins, and from 61% (Tomblin and Buckwalter, 1995) to 29% (Stevenson et al., 1987) for DZ twins.¹¹

The studies Stromswold reviewed included 212 MZ and 199 DZ twin pairs in which at least one member of the pair had a written language disorder, for concordance rates of 74.9% for MZ twins and 42.7% for DZ twins ($z = 6.53$, $p < .00000005$). The studies included 188 MZ and 94 DZ twin pairs in which at least one member of the twin pair had a spoken language disorder, for concordance rates of 84.3% for MZ twins and 52.0% for DZ twins ($z = 5.14$, $p < .00000025$). Overall, the studies included 400 MZ twin pairs and 293 DZ twin pairs, for concordance rates of 79.5% for MZ twins and 45.8% for DZ twins ($z = 8.77$, $p < .00000005$).

The finding that concordance rates were significantly greater for MZ than for DZ twins indicates that genetic factors play a significant role in the development of language disorders. The overall concordance rates for written and spoken language disorders are reasonably similar, with

TABLE 63.2

concordance rates for spoken language disorders being approximately 10 percentage points higher than the rates for written language disorders. However, the fact that the difference between MZ and DZ concordance rates was very similar for written and spoken language disorders is consistent with the hypothesis that genetic factors play an equal role in both types of impairments.

Modes of transmission In a recent review of behavioral genetic studies of spoken language disorders, Stromswold (1998) concluded that most familial language disorders are the product of complex interactions between genetics and environment. In rare cases, however, language disorders may have a single major locus. For example, researchers have reported a number of kindred with extremely large numbers of severely affected family members (e.g., Arnold, 1961; Gopnik, 1990; Hurst et al., 1990; Lewis, 1990) in which transmission seems to be autosomal-dominant with variable rates of expressivity and penetrance. When Samples and Lane (1985) performed a similar analysis on a family in which six of six siblings had a severe developmental language disorder, they concluded that the mode of transmission in that family was a single autosomal recessive gene. If there are multiple modes of transmission for SLI, as the above results seem to indicate, SLI is probably genetically heterogeneous, just as dyslexia appears to be genetically heterogeneous.

The final—and most definitive—method for determining whether there is a genetic basis for familial language disorders is to determine which gene (or genes) is responsible for the language disorders found in these families. Typically, this is done by using linkage analysis techniques to compare the genetic material of language-impaired and normal family members, thereby allowing researchers to determine how the genetic material of affected family members differs from that of unaffected members. Linkage analyses of dyslexic families suggest that written language disorders are genetically heterogeneous (Bisgaard et al., 1987; Smith et al., 1986), with different studies revealing involvement of chromosome 15 (Smith et al., 1983; Pennington and Smith, 1988), the HLA region of chromosome 6 (Rabin et al., 1993), and the Rh region of chromosome 1 (Rabin et al., 1993). Froster and colleagues (1993) have reported a case of familial speech retardation and dyslexia that appears to be caused by a balanced translocation of the short arm of chromosome 1 and the long arm of chromosome 2. Recently, Fisher and colleagues (1998) conducted the first linkage analyses for spoken language disorders, performing genome-wide analyses of the genetic material of the three-generation family studied by Gopnik (1990a) and Hurst and colleagues (1990). They determined that the impairments exhibited by members of this family

are linked to a small region on the long arm of chromosome 7, confirming autosomal dominant transmission with near 100% penetrance. However, it is important to note that in addition to the grammatical deficits described by Gopnik (1990a), affected members of this family also suffer from orofacial dyspraxia and associated speech disorders (see Hurst et al., 1990; Fisher et al., 1998). We cannot, therefore, conclude that the identified region of chromosome 7 necessarily contains a gene or genes specific to language. Clearly, linkage studies must be performed on other families whose deficits are more circumscribed.

At least three distinct relationships could obtain between genotypes and behavioral phenotypes. It is possible (albeit unlikely) that there is a one-to-one relationship between genotypes and phenotypes, with each genotype causing a distinct type of language disorder. Alternatively, there might be a one-to-many mapping between genotypes and phenotypes, with a single genetic disorder resulting in many behaviorally distinct types of language disorders. For example, one MZ twin with a genetically encoded articulation disorder might respond by refusing to talk at all, whereas his cotwin with the same genotype might speak and make many articulation errors. Finally, there may be a many-to-one mapping between genotypes and phenotypes, with many distinctive genetic disorders resulting in the same type of linguistic disorder. For example, SLI children who frequently omit grammatical morphemes (see Leonard, 1998; Stromswold, 1997) might do so because they suffer from an articulation disorder such as dyspraxia which causes them to omit grammatical morphemes that are pronounced rapidly, because they have difficulty processing rapid auditory input such as unstressed, short-duration grammatical morphemes or because they have a syntactic deficit.

Although a single genotype may result in different linguistic profiles and, conversely, different genotypes may result in very similar profiles, researchers should attempt to limit behavioral heterogeneity. Doing so will increase the likelihood of identifying specific genotypes associated with specific types of linguistic disorders. And such focused research would help answer the fundamental question: Is the ability to learn language the result of genetically encoded, linguistically specific operations?

RECOVERY FROM ACQUIRED BRAIN DAMAGE Lesions acquired during infancy typically result in relatively transient, minor linguistic deficits, whereas similar lesions acquired during adulthood typically result in permanent, devastating language impairments (see, for example, Guttman, 1942; Lenneberg, 1967; but see Dennis, 1997, for a critique).¹² The generally more

optimistic prognosis for injuries acquired during early childhood may reflect the fact that less neuronal pruning has occurred in young brains (Cowan et al., 1984), and that the creation of new synapses and the reactivation of latent synapses is more likely in younger brains (Huttenlocher, 1979). Language acquisition after childhood brain injuries typically has been attributed either to recruitment of brain regions adjacent to the damaged perisylvian language regions in the left hemisphere or to recruitment of the topographically homologous regions in the undamaged right hemisphere. According to Lenneberg (1967), prior to puberty, the right hemisphere can completely take over the language functions of the left hemisphere. The observation that infants and toddlers who undergo complete removal of the left hemisphere acquire or recover near-normal language suggests that the right hemisphere can take over *most* of the language functions of the left hemisphere provided the transfer of function happens early enough (Byrne and Gates, 1987; Dennis, 1980; Dennis and Kohn, 1975; Dennis and Whitaker, 1976; Rankin, Aram, and Horwitz, 1981; but see Bishop, 1983, for a critique). Because few studies have examined the linguistic abilities of children who undergo left hemispherectomy during middle childhood, the upper age limit for hemispheric transfer of language is unclear. Right-handed adults who undergo left hemispherectomy typically become globally aphasic with essentially no recovery of language (e.g., Crockett and Estridge, 1951; Smith, 1966; Zollinger, 1935). The observation that a right-handed 10-year-old (Gardner et al., 1955) and a right-handed 14-year-old (Hillier, 1954) who underwent left hemispherectomy suffered from global aphasia with modest recovery of language function suggests that hemispheric transfer of language function is greatly reduced but perhaps not completely eliminated by puberty.

Studies revealing that left hemisphere lesions are more often associated with (subtle) syntactic deficits than are right hemisphere lesions (Aram et al., 1985; Aram, Ekelman, and Whitaker, 1986; Byrne and Gates, 1987; Dennis, 1980; Dennis and Kohn, 1975; Dennis and Whitaker, 1976; Kiessling, Denckla, and Carlton, 1983; Rankin, Aram, and Horwitz, 1981; Thal et al., 1991; Woods and Carey, 1979) call into question the complete equipotentiality of the right and left hemispheres for language, and suggest that regions in the left hemisphere may be uniquely suited to acquire syntax. It should be noted, however, that some studies have not found greater syntactic deficits with left than right hemisphere lesions (e.g., Bassler, 1962; Feldman et al., 1992; Levy, Amir, and Shalev, 1992). These studies may have included children whose lesions were smaller (Feldman et al., 1992) or in different locations than those in studies in which a hemi-

spheric difference for syntax was found. Bates and colleagues (1997) have examined early language acquisition in children who suffered unilateral brain injuries prior to 6 months of age. Parents of 26 children (16 with left hemisphere lesions, 10 with right hemisphere lesions) between the ages 10 and 17 months completed the MacArthur Communicative Development Inventory. According to parental report, overall, children with brain injuries had smaller vocabularies than normal children.¹³ Consistent with Mills, Coffey-Corina, and Neville's (1997) ERP findings that the right hemisphere is particularly crucial in the perception of unknown words by children between 13 and 20 months of age, children with right hemisphere lesions had smaller expressive vocabularies and used fewer communicative gestures than children with left hemisphere lesions (Bates et al., 1997). Parental report for 29 children (17 with left hemisphere lesions, 12 with right hemisphere lesions) between 19 and 31 months of age generally revealed that children with left hemisphere lesions had more limited grammatical abilities than children with right hemisphere lesions (Bates et al., 1997). This was particularly true for children with left temporal lesions. Bates and colleagues also compared the mean length of utterance (MLU) in free speech samples for 30 children (24 with left-hemisphere lesions, 6 with right hemisphere lesions) between the ages of 20 and 44 months. Consistent with the parental report results, children with left hemisphere lesions had lower MLUs than children with right hemisphere lesions. MLUs for children with left temporal lesions were especially depressed compared to children without left temporal injuries.

In children who suffer from partial left hemisphere lesions rather than complete left hemispherectomies, language functions could be assumed by adjacent undamaged tissues within the left hemisphere or by homotopic structures in the intact right hemisphere. Results of Wada tests (in which lateralization of language is determined by testing language function when each hemisphere is temporarily anesthetized) indicate that children with partial left hemisphere lesions often have language represented bilaterally or in the right hemisphere (Matteer and Dodrill, 1983; Rasmussen and Milner, 1977). However, one ERP study suggests that children with partial left hemisphere lesions are more likely to have language localized in the left hemisphere than the right hemisphere (Papanicolaou et al., 1990). There are a number of possible reasons for this discrepancy, including differences in the types of linguistic tasks used in the ERP and Wada studies and possible differences in sizes and sites of left hemisphere lesions in the children studied. In addition, it is possible that the discrepancy is due to the fact that most of the children in the ERP study acquired their lesions after age 4. Furthermore, the extent to which

any of the children in the ERP study ever exhibited signs of language impairment is unclear.

Despite disagreement about the details of language recovery after postnatally acquired left hemisphere lesions, the following generalizations can be made (but see Dennis, 1997). Behaviorally, the prognosis for recovery of language is generally better for lesions acquired at a young age, and syntactic deficits are among the most common persistent deficits. If a lesion is so large that little or no tissue adjacent to the language regions of the left hemisphere remains undamaged, regions of the right hemisphere (presumably homotopic to the left hemisphere language areas) can be recruited for language. The essentially intact linguistic abilities of children with extensive left hemisphere lesions are particularly remarkable when contrasted with the markedly impaired linguistic abilities of SLI children who have minimal evidence of neuropathology on CT or MRI scans. Perhaps the reason for this curious finding is that, although SLI children's brains are not deviant on a macroscopic level, SLI brains may have pervasive, bilateral microscopic anomalies such that no normal tissue can be recruited for language function. One piece of data that supports this hypothesis is found in the results of an autopsy performed on a boy who suffered a severe cyanotic episode at 10 days of age. This child subsequently suffered from pronounced deficits in language comprehension and expression until his death (from mumps and congenital heart disease) at age 10. Autopsy revealed that the boy had bilateral loss of cortical substance starting at the inferior and posterior margin of the central sulci and extending backward along the course of the insula and sylvian fissures for 8 cm on the left side and 6 cm on the right side (Landau, Goldstein, and Kleffner, 1960). Perhaps this child did not "outgrow" his language disorder because these extensive bilateral lesions left no appropriate regions that could be recruited for language.

Summary

Evidence from normal and abnormal language acquisition suggests that innate mechanisms allow children to acquire language. Given adequate early exposure to language, children's language development proceeds rapidly and fairly error-free, despite little or no instruction. The brain regions that permit this development seem to be functionally and anatomically distinct at birth, and may correspond to what linguists call Universal Grammar. To account for the fact that mastery of a particular language does not occur without exposure to that language during infancy or early childhood, it is possible that the neural fine-tuning associated with learning a language's particular parameters must take place during a

period of high neural plasticity. There is some evidence to suggest that the structures and operations involved in language are at least partially anatomically and functionally modular and apparently have no nonlinguistic counterparts. One possibility is that children have innate mechanisms that predispose them to perceive categorically linguistic stimuli such as phonemes, words, syntactic categories, and phrases and exposure to these types of linguistic stimuli facilitates the neural fine-tuning necessary for normal language acquisition. For example, some innate mechanisms might predispose children to assume that certain types of meanings and distinctions are likely to be conveyed by morphemes. Also, some innate mechanisms might specifically predispose children to distinguish between syntactic categories that allow for free generalization (lexical categories) and those that do not (functional categories). These innate mechanisms may allow children's brains to solve the otherwise intractable induction problems that permeate language acquisition.

In the future, fine-grained linguistic analyses of the speech of language-impaired children may be used to distinguish between different types of SLI. Linkage studies of SLI may tell us which genes code for the brain structures that are necessary for language acquisition. MRI's exquisite sensitivity to white matter/gray matter distinctions means that MRI could be used to look for more subtle defects associated with developmental language disorders, including subtle disorders arising from neuronal migration or dysmyelination (Barkovich and Kjos, 1992; Edelman and Warach, 1993). Furthermore, the correlation between myelination and development of function (Smith, 1981) means that serial MRIs of normal children, SLI children, and WS children could shed light on the relationship between brain maturation and normal and abnormal language development. Finally, functional neuroimaging techniques such as ERP, PET, and fMRI may help to answer questions about the neural processes that underlie language and language acquisition in normal children, SLI children, WS children, children with left hemisphere lesions, and children who are exposed to language after the critical period.

ACKNOWLEDGMENTS Preparation of this chapter was supported by a Merck Foundation Fellowship in the Biology of Developmental Disabilities and a Johnson & Johnson Discovery Award. I am grateful to Willem Levelt for his support during the writing of this chapter and to Anne Christophe, Steve Pinker, and Myrna Schwartz for their comments on earlier drafts. A similar chapter will appear in E. Lepore and Z. Pylyshyn (eds.), *What Is Cognitive Science?* Oxford: Basil Blackwell.

NOTES

1. Children differ dramatically in the rate of acquisition. For example, Brown (1973) and Cazden (1968) investigated when three children mastered the use of 14 grammatical

- morphemes. Although all three children eventually obtained competence in the use of the third-person singular verbal inflection -s (as in *he sings*) and all three reached this point after they achieved adult-like performance on plurals and possessives, one of the children reached competence at 2;3 (2 years and 3 months), one at 3;6, and one at 3;8. Similar findings concerning individual differences have been found in the rate of acquisition of questions (Stromswold, 1988, 1995) and auxiliaries (Stromswold, 1990a,b) as well as datives, verb particles, and related constructions (Snyder and Stromswold, 1997; Stromswold, 1989a,b). A number of studies have also reported that children's vocabulary development can vary greatly in both rate and style (e.g., Nelson, 1973; Goldfield and Reznick, 1990).
2. Although the observation that the pattern of acquisition varies depending on the structure of the language is consistent with functionalist accounts of language acquisition (e.g., MacWhinney, 1987), such observations can be accounted for within generative theories if one makes the assumption that children must receive a certain amount of positive data from the input in order to set parameters (for P&P) or rank constants (for OT).
 3. Throughout this chapter, ungrammatical sentences are indicated with an asterisk (*).
 4. There are 23! logically possible unique orders of all 23 auxiliaries. The total number of orders including sets with fewer than 23 auxiliaries is considerably bigger. Because the 23! term is the largest term in the summation, it serves as a lower bound for the number of unique orders and suffices as an estimation of the number of orders.
 5. The mere existence of cerebral asymmetries does not prove that there is an innate basis for language, as other mammals also exhibit such asymmetries.
 6. Fifteen of the 20 parents and 4 of the 10 siblings had language deficits. The controls had no personal or family history of language impairment or delay.
 7. These were not, however, the same children who did poorly on Tallal and Piercy's (1973a,b) auditory processing task.
 8. Clinicians and researchers generally agree that considerable diversity exists in the behavioral profiles and manifestations of children diagnosed with SLI and that it is important to distinguish between various subtypes of SLI. However, no system for classifying subtypes of SLI is generally accepted (Stromswold 1997).
 9. The term "proband" refers to an affected individual through whom a family is brought to the attention of an investigator.
 10. The variance is due in large part to what was counted as evidence of language impairment in families. As indicated in table 63.1, some studies considered family members to be affected only if they suffered from a spoken language disorder, whereas other studies counted as affected any family members having a history of dyslexia, nonlanguage learning disabilities, or school problems.
 11. In this chapter, all concordance rates are for proband-wise concordance rates. Proband-wise concordance rates are calculated by taking the number of affected individuals in concordant twin pairs (i.e., twin pairs where both twins are affected) and dividing this number by the total number of affected individuals.
 12. In a recent review of research on children whose brain injuries occurred after the onset of language acquisition,

Dennis (1997) argues that the prognosis is no better for children than adults once the etiology of the brain injury is taken into account.

13. Bates and colleagues (1997) report large variance in language abilities among their lesioned subjects, with some of the children's language being at the high end of the normal and other children suffering from profound impairments. This probably reflects, at least in part, variations in the size and sites of the lesions among their subjects.

64 Computational Modeling of Language Disorders

ELEANOR M. SAFFRAN, GARY S. DELL, AND MYRNA F. SCHWARTZ

ABSTRACT Computational modeling of aphasia and related language disorders is a relatively new aspect of cognitive neuroscience. This chapter reviews three recent models that represent different domains and architectures: a model of aphasic sentence comprehension based on a hybrid/symbolic connectionist architecture (Haarmann, Just, and Carpenter, 1997), a localist connectionist model of lexical access by aphasic speakers (Dell et al., 1997), and a parallel-distributed processing model of deep dyslexia (Plaut and Shallice, 1993). The models share the key assumption that the complexities of language disorders emerge from the processes that underlie normal performance. Each model processes information by spreading activation and attributes pathological symptoms to lesions in the mechanisms that shape activation patterns. The models give a good account of several basic phenomena in language pathology, including variation in symptom patterns with severity of damage, the graded, probabilistic nature of errors, and relationships among error types. Although the models have made good progress in simulating the behavioral data associated with aphasia, they do not, as yet, speak to the brain-behavior mapping for language.

Over the course of the past decade, the modeling of cognitive processes has shifted from the “box-and-arrow” information flow diagram toward a more computational approach. Computational modeling offers a number of advantages: (1) The model must be translated into a computer program, forcing theorists to be explicit about their theoretical assumptions; (2) it is possible to run experiments in the form of simulations, allowing for a determination of a model’s descriptive adequacy and an understanding of the mechanisms by which it accommodates or fails to accommodate the data; (3) simulations occur over time, providing the opportunity to examine dynamic aspects of processing that were difficult to capture in flow diagram models; (4) and there is the hope of simulating the architecture of real networks of neurons, a long-range goal currently far from realization.

Although most computational modeling has been concerned with normal cognitive processes, there is an increasing effort to perturb these models in ways that simulate the pathologies produced by damage to the brain. Lesioning the model—weakening connections, deleting units, increasing noise or the rate of decay of activation—generates abnormal response patterns. The effort to simulate actual behavior patterns associated with brain damage provides another means of testing the validity of the model, and, perhaps, a source of new insights into the pathological condition.

In this chapter, we examine several attempts to lesion computational models of language processing to simulate the language deficits of aphasics. To provide an indication of the range of approaches and empirical domains, we consider three different types of models, each concerned with a different aspect of language behavior. The first is the simulation of sentence comprehension impairments on a hybrid symbolic/connectionist model developed by Just and Carpenter and their colleagues (Just and Carpenter, 1992; Haarmann, Just, and Carpenter, 1997). In the symbolic approach, an early development in computational modeling (e.g., Anderson, 1983), rules are instantiated as procedures: If input A satisfies condition X, then transform A to B. The sentence comprehension model effects such transformations by transmitting activation from one node to another, as in connectionist networks; the amount of activation available to the comprehension system is a critical component of the model. Next we present simulations of disordered picture naming on the localist connectionist model of word retrieval developed by Dell and his colleagues (Dell, 1986; Dell and O’Seargha, 1991; Dell et al., 1997). The model employs activation flow from semantic to phonological levels of representation to simulate lexical retrieval. It is a localist model in that each informational element (semantic feature, lexical unit, phoneme) is represented as a unitary node. The connections between units are determined a priori and hardwired into the model. The localist approach is distinguished from the third model we present, which is a parallel-distributed processing (PDP) model of reading. This model, developed by Plaut and Shallice

MYRNA F. SCHWARTZ Moss Rehabilitation Research Institute, Philadelphia, Pa.

(1993; Hinton and Shallice, 1991), addresses the phenomena that distinguish the acquired reading disorder known as deep dyslexia. This model has two salient features: (1) Representations are distributed in that, except for input and output units, a single node does not encode a particular unit of information; (2) connections are not hard-wired, but random to begin with and modified over the course of learning trials. In addition to describing the models and comparing the results of simulations to the behavior patterns associated with the relevant disorders, we consider both the achievements and the limitations of each approach.

Sentence comprehension: A hybrid (symbolic/connectionist) model

Sentence comprehension is a complex process. It involves perceiving the successive words in the sentence, retrieving semantic and syntactic specifications for these words, assembling syntactic structure, and integrating lexical and syntactic information to yield a semantic and ultimately pragmatic interpretation. There have been attempts to model the process in its entirety using a localist framework (e.g., Cottrell, 1985), as well as efforts to build PDP models that focus on its syntactic (e.g., Elman, 1991) or semantic (e.g., McClelland, St. John, and Taraban, 1989) aspects. The model we examine here represents an attempt to deal with the sentence comprehension process as a whole. This model, described by Haarmann, Just, and Carpenter (1997)—henceforth HJC—is the most recent version of the CAPS/CC READER model developed by Just and Carpenter (1992) and their colleagues.

The model instantiates a capacity theory of individual differences in sentence comprehension. Support for this theory comes from the reading span task (Daneman and Carpenter, 1980), in which subjects are required to read a set of unrelated sentences and, in addition, to hold the last word of each sentence in memory. Subjects with high and low word spans, as assessed by the number of terminal words they were able to report, performed differently on sentence comprehension measures; in particular, differences between high and low span subjects increased as a function of syntactic complexity (e.g., Just and Carpenter, 1992). These findings motivated the assumption that there is a fixed working memory capacity for language processing that differs across individuals; subjects with high spans, as measured by the reading span task, have greater capacity than those with low spans.

The range of individual differences that HJC sought to account for includes the effects of brain damage on language function, which in most cases involve deficits in sentence comprehension. The variables that ad-

versely affect sentence understanding in aphasia include the following (see accompanying box):

i. Semantic reversibility, or the absence of semantic constraints on thematic role assignment [the sentence in (1b) is reversible, whereas (1a) is not]. Aphasics often perform better on nonreversible sentences, indicating that they are placing significant weight on semantic constraints.

ii. Syntactic complexity, which includes factors such as noncanonical order of the noun phrases [compare (1b) and (1c), where the agent-patient order typical of English sentences applies in (1b) but not in the passive sentence (1c)]. Aphasics tend to do better on sentences with canonical word order.

iii. The occurrence of intervening words between a noun phrase and the information required to assign it a thematic role [compare (1b) and the object relative construction in (1d)].¹

iv. An increase in the number of noun arguments and/or verbs, as in the dative construction (1e) and in sentences with multiple clauses (1f).

While these variables have been most extensively studied in patients with syntactic deficits in production (agrammatic aphasics), sensitivity to these factors is also evident in data for groups of unselected aphasics. For example, Caplan and Hildebrandt (1988) found that aphasic performance over a range of reversible sentence types decreases over the constructions exemplified in (1b)–(1f), except that datives (1e) are generally easier than object relatives (1d).

- | | |
|-----|--|
| 1a. | The dog buried the bone. |
| 1b. | The cat chased the dog. |
| 1c. | The dog was chased by the cat. |
| 1d. | The dog that the cat chased was black. |
| 1e. | The elephant showed the giraffe the tiger. |
| 1f. | The elephant that the giraffe pushed kicked the tiger. |

One conclusion that has been drawn from such findings is that a unitary impairment underlies the sentence comprehension deficits of aphasics. Two causal factors proposed by a number of investigators are time and capacity. The concern with timing reflects the consideration that comprehension entails coactivation of the successive elements of the sentence at some level of representation. If processing is slowed, so that information cannot be maintained over the span of the sentence, comprehension is likely to break down. A decrease in processing rate is the explicit focus of computational models of aphasic sentence comprehension proposed by Gigley (1983) and

by Haarmann and Kolk (1991), and has been implicated in other accounts of aphasic performance (e.g., Swinney et al., 1996). Timing and capacity are interrelated in the account of aphasic sentence comprehension that HJC instantiated in their computational model. Other capacity-based accounts are presented in Blackwell and Bates (1995) and Frazier and Friederici (1991).

HJC assume that aphasics have insufficient verbal working memory capacity to sustain normal comprehension performance. This assumption follows from an earlier study by Miyake, Carpenter, and Just (1994), who demonstrated that speeding up presentation time [using the rapid serial visual presentation (RSVP) paradigm], elicited aphasic-like performance patterns in normal subjects. Although these subjects performed at higher levels than aphasics, their behavior across sentence types replicated the effects of syntactic complexity and verb and argument number that emerged in Caplan and Hildebrandt's (1988) studies of aphasics. One consequence of speeded presentation under RSVP is that less processing time can be dedicated to each element, effectively limiting the buildup of activation; the effect is therefore similar to that of lowering capacity. On the basis of their results in normal subjects, Miyake and colleagues argued that reduction in working memory capacity underlies the sentence comprehension deficits of aphasics. Citing Caplan and Hildebrandt's finding that aphasics' comprehension performance was highly correlated with the overall severity of the language impairment, Miyake and co-workers reasoned that severity was a reflection of decreased capacity.

The model combines features of symbolic production-action and connectionist models. The production-action feature is the instantiation of a procedural memory that embodies a set of rules (e.g., Anderson, 1983). When the conditions for a particular procedure are met, the appropriate operation is executed by means of activation flow, in the manner of connectionist models. For example, the occurrence of a preposition (e.g., *to*, *by*) signals the beginning of a prepositional phrase, indicating that a noun phrase must follow. When a node signifying the identification of a preposition has been activated, activation flows to the node that represents the syntactic constituent "noun phrase complement." This structure is then integrated into the syntactic structure for the sentence. The flow of activation does not occur all at once but over a number of time steps, as in connectionist networks. Figure 64.1 provides an overview of the HJC model. Note that the model includes a lexical component, which provides access to the semantic and syntactic properties of the words in the sentence; a parser, which constructs a hierarchical phrase tree along the lines of X-bar grammar (e.g., Jackendoff, 1977); and a

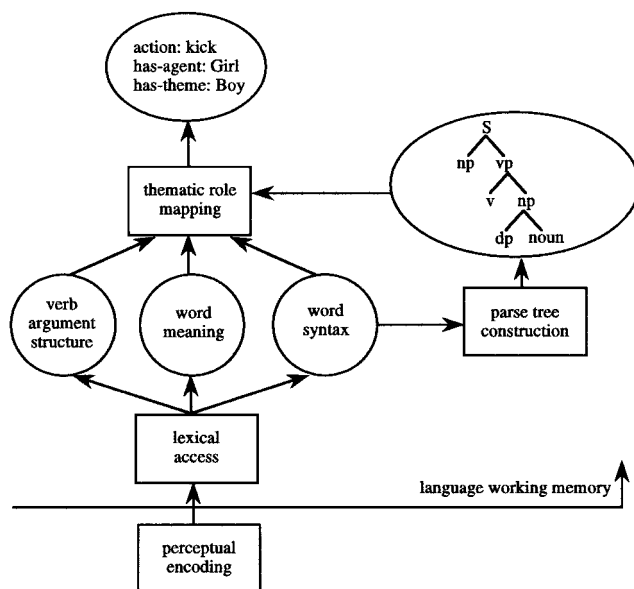

FIGURE 64.1 Overview of the HJC model. (Adapted from Haarmann, Just, and Carpenter, 1997.)

thematic role component, which utilizes lexical syntactic information—together with the output of the parser—to map noun phrase constituents onto the roles specified by the verb(s) in the sentence (e.g., agent, patient, goal). The components of the model operate in parallel. Sentence comprehension is assessed by examining the activation levels of the filled thematic role slots.

Verbal working memory capacity in this model is defined in terms of activation. The model's core assumption is that activation is a limited resource that is used both to perform linguistic operations and to maintain the products in an active form for further processing. The model does not distinguish between processing and maintenance functions: If processing operations require more capacity, less is available for maintenance, and vice versa. An activation shortage can arise when storage and processing exceed capacity, in which case "the activations that are associated with individual working memory elements and with individual propagation amounts are scaled down so that the total activation (i.e., the capacity) is allocated. . . . This results in both forgetting and slower processing." (Haarmann, Just, and Carpenter, 1997, p. 87)

The underlying principle is that aphasic disorders arise from a pathological reduction in working memory. The degree of severity of the aphasic deficit varies with the amount of reduction. The model predicts (i) a syntactic complexity effect and (ii) an interaction between syntactic complexity and the extent to which working memory capacity is decreased below normal levels. The assignment of thematic roles is especially capacity-demanding,

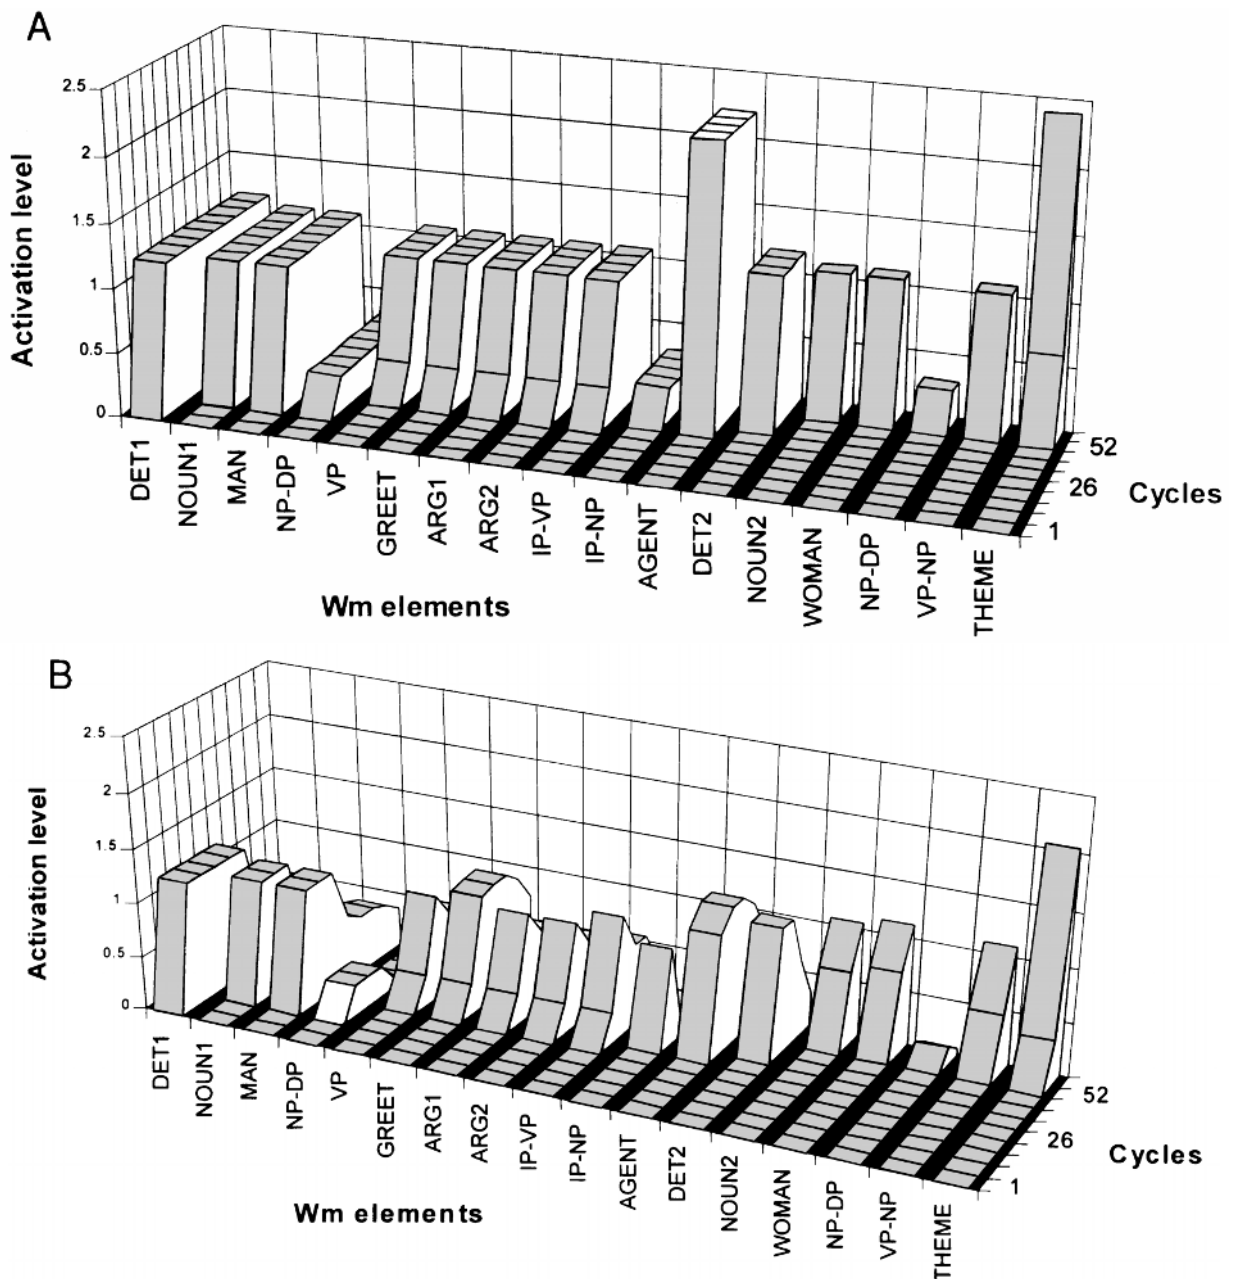

FIGURE 64.2 Example of the HJC model's processing of a sentence with high (above) and low capacity: Activation level for elements in working memory as a function of time cycles

for the sentence, "The man greets the woman." (Reprinted with permission from Haarmann, Just, and Carpenter, 1997.)

which may account for the vulnerability of this process in aphasia (e.g., Linebarger, Schwartz, and Saffran, 1983).

In simulations, the model required a working memory capacity equal to 30 to achieve perfect comprehension over a range of sentence types. To simulate aphasic comprehension, HJC decreased capacity below that level. This reduction has an impact on processing as well as the ability to maintain information over the course of the sentence. Figure 64.2 illustrates the model's processing of an active sentence under high (capacity = 30) and

low working memory (capacity = 10) conditions. It is evident that, although the activation of elements at the beginning of the sentence remains high in the case of the high-capacity simulation, earlier elements decay over time under the low-capacity condition. In the latter case, the level of thematic role binding does not achieve threshold (set at an activation level of 2) for either agent or theme, and comprehension fails.

To examine the model's ability to simulate aphasic performance, HJC tested its comprehension of a range of

TABLE 64.1
Sentence types used by Caplan and colleagues (1985)*

Sentence Types
Active (A) The rat hit the dog.
Passive (P) The rat was hit by the dog.
Cleft-subject (CS) It was the rat that hit the dog.
Cleft-object (CO) It was the rat that the dog hit.
Dative (D) The rat gave the dog to the cow.
Dative passive (DP) The rat was given to the dog by the cow.
Conjoined (C) The rat hit the dog and kissed the cow.
Right-branching subject relative or object-subject relative (OS) The rat hit the dog that kissed the cow.
Center-embedded object relative or subject-object relative (SO) The rat that the dog hit kissed the cow.

*Table taken from Haarmann, Just, and Carpenter, 1997.

sentence types with working memory capacity set at half the optimal level (15). The sentence types (see table 64.1) were those used in Caplan and Hildebrandt's (1988) study of aphasic comprehension (and by Caplan, Baker, and Dehaut, 1985). Figure 64.3 compares the simulation data to the performance of Caplan and Hildebrandt's aphasics. For the most part, the simulations capture the order of difficulty in the aphasic data, as well as the effect of severity of the aphasic impairment. Additional simulations carried out by HJC included an examination of performance on

actives and passives at two different levels of capacity reduction. The relative difficulty of passives increased under both manipulations. The capacity reduction effect accords with data reported for agrammatic aphasics at different severity levels (see Kolk and van Grunsven, 1985).

The simulations reveal that the model is reasonably successful in capturing the relative difficulty of sentence types, as assessed by the average performance of a heterogeneous group of aphasics, as well as the performance of normals under RSVP. To our knowledge, this is the only computational model that attempts to deal with effects of syntactic complexity in both normals and aphasics. Another strength of the model is that it provides a simple account of variability in performance, both within each group of subjects and between groups. At a more general level, Just and colleagues deserve credit for tackling a very complex problem with empirical data and computational techniques that integrate major perspectives in cognitive science: linguistic theory, production systems, and connectionism.

However, there are reasons to question the model's basic assumption that comprehension patterns in aphasic subjects reflect capacity limitations (see Martin, 1995; Caplan and Waters, 1995; and the response by Miyake, Carpenter, and Just, 1995). It may be that the problem lies not in capacity per se, but in the inefficiency of particular operations. Some aphasic patients have more difficulty with lexical processing than others, some are more affected by padding sentences with extra material (Schwartz et al., 1987), and some rely very heavily on semantic constraints (Saffran, Schwartz, and Linebarger, 1998). The greater the severity of the language impairment, the more likely that the patient has multiple deficits. As a result of such deficits, aphasics may devote capacity to the impaired domains, diminishing the resources available for processing and maintaining sentential information in memory. This formulation salvages

FIGURE 64.3 Data on aphasic sentence composition from Caplan and Hildebrandt (1988) and simulated data from the HJC model. AZ, active; CS, cleft-subject; P, passive; D, dative;

CO, cleft-object; OS, object-subject relative; C, conjoined; DP, dative passive; SO, subject-object relative. (Reprinted with permission from Haarmann, Just, and Carpenter, 1997.)

the assumption of a common pool of resources that is central to HJC's approach, while acknowledging that the source of the deficit may vary from one patient to another. However, the possibility that specific deficits are the direct cause of patients' failure on the more difficult sentences cannot be excluded. In view of this possibility, simulating the performance of a heterogeneous group of aphasics does not constitute a particularly strong test of the model. A more rigorous test would involve an attempt to simulate individual patients' performance levels across a range of sentence types.

There are also experimental data that challenge the core assumptions of the model. Rochon and her colleagues have examined sentence processing in patients with Alzheimer's disease, whose reading spans, as assessed by the Daneman and Carpenter (1980) measure, are limited to one or two items (Rochon, Waters, and Caplan, 1994). These patients show little effect of the syntactic complexity factors that impede aphasic comprehension, although they are adversely affected by increasing the number of propositions in the sentence.

Finally, the model is incomplete in that it fails to deal with effects of semantic constraints on comprehension. These influences have emerged in studies of normal comprehension (e.g., MacDonald, Pearlmutter, and Seidenberg, 1994), as well as in the effects of semantic reversibility on aphasic performance (e.g., Caramazza and Zurif, 1976). The force of these constraints is dramatically evident in patients' insensitivity to assertions that violate them. Saffran, Schwartz, and Linebarger (1998) demonstrated that aphasics were only 57 percent correct in judging the plausibility of simple active sentences that contained semantic incongruities (e.g., *The children frightened the movie*). This effect emerged in patients whose performance was highly sensitive to syntactic complexity, as well as in those who showed little influence of this factor. In normals, King and Just (1991) found that high span subjects were more likely to show semantic influences than low span subjects, suggesting that the interaction between syntax and semantics requires working memory capacity (Just and Carpenter, 1992). If aphasics are considered to have less capacity than low span normals, they should not demonstrate this interaction. Alternatively, the semantic effect may have a different locus in the aphasics. In either case, it is clear that the model in its current form fails to account for this salient aspect of aphasic comprehension.

Lexical retrieval in picture naming: An interactive activation model

To a first approximation, one can conceptualize the production of a sentence as comprehension in reverse. The

speaker's task is to formulate a message that specifies the thematic content of the sentence, select the words and syntactic form (phrase structure) suitable to express this content, order the words in a manner dictated by the phrase structure, and encode this in a phonetic form for articulation.

It occasionally happens in normal speech that something goes awry and the wrong word is uttered, or the right word is uttered at the wrong time or with the wrong pronunciation. Close study of these sorts of speech errors has given rise to an influential theory of production that incorporates two informationally encapsulated stages of lexical retrieval (Fay and Cutler, 1977; Fromkin, 1971; Garrett, 1975; Levelt, 1989; Levelt, Roelofs, and Meyer, 1998). The first stage is controlled by a structure that represents sentence meaning and that is sensitive to the semantic-syntactic properties of words and not to their phonological form. The second stage is controlled by a structure that represents surface phrasal geometry and that is responsive only to the phonological properties of words. The controlling structures may be characterized as frames containing slots that specify and receive the retrieved lexical content (Bock and Levelt, 1994; Dell, 1986; Garrett, 1975; MacKay, 1972; Shattuck-Hufnagel, 1979).

Most theoretical accounts of impaired word retrieval in aphasia similarly separate semantic and phonological stages of retrieval (Butterworth, 1989; Caramazza, 1988; Ellis, 1985; Garrett, 1984; Saffran, 1982; Schwartz, 1987). Aphasics produce errors in both connected speech and single word tasks, and many of their errors, like those of normals, are related to the target in meaning (semantic errors, like *dog* for *cat* or form (formal errors like *mat* for *cat*; neologisms like *dat* for *cat*) (Buckingham, 1980). Patients can be categorized according to whether their errors are mostly of one type or another.

The claim that the stages of word retrieval are informationally encapsulated, hence modular, has not gone unchallenged. Interactive activation models have been proposed as alternative accounts of lexical retrieval in normality (Dell, 1986; Dell and Reich, 1981; Harley, 1984; Houghton, 1990; Stemberger, 1985) and pathology (Dell et al., 1997; Ellis, 1985; Martin and Saffran, 1992; Martin et al., 1994; Schwartz et al., 1994; Wilshire and McCarthy, 1996). The hallmark of interactive activation models is their nonmodularity. Because activation spreads continuously and bidirectionally, early stages of processing are influenced by information from later stages, and vice versa (McClelland and Rumelhart, 1981).

Do semantic and phonological information sources interact during word retrieval? There is evidence both pro and con. Although most word substitution errors

FIGURE 64.4 The DSMSG model. Only the features of the target “cat” are shown. (Reprinted with permission from Dell et al., 1997.)

bear either a semantic or phonologic relation to the target, the frequency of mixed (semantic + phonologic) word substitution errors (e.g., *rat* for *cat*) is significantly higher, for both normals and aphasics, than what would be expected if semantic and phonological factors were associated with strict serially ordered modular processes (Dell and Reich, 1981; Harley, 1984; Martin, Weisberg, and Saffran, 1989; Martin et al., 1996). But whereas the mixed error evidence is consistent with interaction (see, however, Levelt, Roelofs, and Meyer, 1999), experiments on the time course of semantic and phonological retrieval in lexical access show conclusively that the interaction, if it exists at all, must be limited. At the earliest points, processing appears to be exclusively semantic; however, just prior to articulation, the retrieval of phonological information completely dominates that of semantic information (Dell and O’Seaghdha, 1991; Levelt et al., 1991; Peterson and Savoy, 1998; Schriefers, Meyer, and Levelt, 1990).

The DSMSG model [from Dell, Schwartz, Martin, Saffran, and Gagnon (1997)] is a spreading activation model of retrieval in which interactivity is combined with a two-stage selection process (see also Dell and O’Seaghdha, 1991). In effect, this model represents a compromise between strictly modular accounts (e.g., Levelt et al., 1991) and more fully interactive ones (e.g., Harley, 1984; Stemmer, 1985).

Like other interactive activation models of lexical processing, the DSMSG model has lexical knowledge represented in a layered network of units or nodes. Nodes are not repositories for stored information, but rather simple, neuron-like devices that collect, summate, and transmit activation. An important distinction among connectionist models is whether they use a local or distributed style of representation. In localist models, nodes

stand in one-to-one correspondence with psychologically meaningful properties. Such is the case in the DSMSG model, where the top level in the network represents semantic features, the middle level represents known words, and the bottom level represents phonemes (figure 64.4).

All connections in the DSMSG model are excitatory and bidirectional. Each node’s activation level is a positive real number, determined by a linear activation updating function that includes a decay factor (q) and normally distributed noise. All connections in the model have the same weight (designated by p), meaning that for any two connected nodes i and j , node i transmits a proportion p of its activation to node j at each time step. The values of p and q are preset; there is no learning in this model.

In addition to the activation updating function, there are external sources of activation that influence a node’s level of activation. At the outset of a trial, external activation is applied to the semantic features that correspond to the target (here designated as *cat*). Activation is allowed to spread freely for a specified number of time steps (n), whereupon the most highly activated word node is selected. This is the first of two selection steps; it entails linking the word node to a syntactic frame (a single noun frame, in the case of naming) and giving it an external boost of activation. Activation continues to spread for another n time steps. This is followed by step-2 selection, in which the most activated onset, vowel, and coda phonemes are linked to their respective slots in the phonological frame (a CVC—or consonant-vowel-consonant-frame, in this model) and their activation levels are boosted. This ends the trial. If the model selects *cat* at step 1 and /k/, /æ/ and /t/ at step 2, it has performed correctly. Otherwise it has made an error.

Mis-selections at step 1 can give rise to semantic, formal, mixed, or unrelated errors. Semantic errors (*dog* for *cat*) are encouraged by the overlap in semantic features (see figure 64.4). Formal errors (*mat* for *cat*) are encouraged by bottom-up feedback from the primed phonemes (/æ/, /t/). Mixed competitors (*rat* for *cat*) benefit from both top-down and bottom-up activation. Unrelated competitors (*fog* for *cat*) benefit from neither of these, but in a noisy system, they will sometimes be selected, thereby creating unrelated errors. Mis-selections at step 2 primarily give rise to neologisms (*dat* for *cat*), but word errors may also arise at this step, when the substituted phoneme happens to create another word (*rat*; *mat*).

The frequency with which the model makes various types of error is in large measure determined by its network structure. Dell and colleagues used a very small network, but they made sure that its structure resembled the error opportunities of the English lexicon, as used in naming experiments. The error opportunities associated with a lexicon are the distribution of errors that would occur if output consisted of random phonologically legal strings. Thus, the model affords many opportunities for neologisms, unrelated words, and formals, and fewer opportunities for semantic and mixed. This plays an important role in the simulation of the aphasics' data, as will be seen.

In their first simulation, Dell and colleagues fit the model to the performance of normal speakers (controls) performing the 175-item Philadelphia Naming Test (PNT) (Roach et al., 1996). Both the controls and the model were correct on a very high proportion of the trials; and when they erred, they made mostly semantic and mixed errors (see table 64.2).
